Effect of Atrial Natriuretic Factor on Calcium Fluxes in Adrenal Glomerulosa Cells

MASAO TAKAGI, MARI TAKAGI, ROBERTO FRANCO-SAENZ, DAVID SHIER, AND PATRICK J. MULROW

SUMMARY We studied the effect of atrial natriuretic factor (ANF) on calcium influx and efflux in rat adrenal glomerulosa cells stimulated by angiotensin II (Ang II) or potassium ion, and observed how ANF inhibits the initial and sustained phases of the aldosterone response to Ang II or K⁺ using a superfusion system of dispersed adrenal glomerulosa cells. K⁺ (8 mM) significantly increased Ca²⁺ influx rate compared with basal rate (0.91 ± 0.10 vs 0.42 ± 0.04 nmol/min/10⁶ cells; p < 0.01). ANF (10⁻⁸ M) did not inhibit the K⁺-induced increase in Ca²⁺ influx rate (0.99 ± 0.18 nmol/min/10⁶ cells). Ang II (10⁻⁹ and 10⁻⁸ M) stimulated Ca²⁺ influx rate (10⁻⁹ M Ang II, 0.62 ± 0.02; 10⁻⁸ M Ang II, 0.71 ± 0.09 vs basal, 0.44 ± 0.03 nmol/min/10⁶ cells; p < 0.05), while ANF (10⁻⁸ M) did not change the Ca²⁺ influx rate increased by Ang II (ANF + 10⁻⁹ M Ang II, 0.62 ± 0.06; ANF + 10⁻⁸ M Ang II, 0.69 ± 0.14 nmol/min/10⁶ cells). In the Ca²⁺ efflux study ANF (10⁻⁸ M) was perfused through the cells 10 minutes before the start of perfusion with Ang II (10⁻⁹ M) or K⁺ (12 mM). The peak Ca²⁺ fractional efflux ratio elicited by Ang II or K⁺ did not change in the presence of ANF (K⁺, 1.374 ± 0.051 vs K⁺ + ANF, 1.388 ± 0.011; Ang II, 1.432 ± 0.066 vs Ang II + ANF, 1.394 ± 0.017). The stimulatory effects of Ang II and K⁺ and the inhibitory effect of ANF on aldosterone production were more potent in the superfusion system of dispersed adrenal glomerulosa cells than in the static incubation system. ANF inhibited aldosterone production in both the initial phase and the sustained phase. These results suggest that ANF does not affect Ca²⁺ influx or efflux in rat adrenal glomerulosa cells and that the inhibitory effect of ANF must occur after the generation of the Ca²⁺ signal in the cells. (Hypertension 11: 433-439, 1988)

KEY WORDS • atrial natriuretic factor • aldosterone • calcium influx • calcium efflux

Atrial natriuretic factor (ANF) inhibits aldosterone production in adrenal glands in vitro and in vivo.¹⁻³ Infusion of ANF lowers plasma aldosterone levels in humans.⁶⁻⁷ ANF also has smooth muscle-relaxing activities.⁵,⁹ The intracellular mechanisms mediating the actions of ANF are still unknown. The calcium messenger system mediates the cellular response to some regulators in these two target cells for ANF, namely, adrenal glomerulosa cells and vascular smooth muscle cells.¹⁰ We examined whether ANF affects the calcium messenger system in adrenal glomerulosa cells. The response of aldosterone production in adrenal glomerulosa cells has two phases (i.e., initial and sustained). The mechanism by which angiotensin II (Ang II) stimulates the two phases differs from those of potassium ion and adrenocorticotropic hormone (ACTH).¹¹ However, these three secretagogues increase Ca²⁺ influx and efflux in the glomerulosa cells.¹¹⁻¹³ In the present study, we evaluated the effect of ANF on Ca²⁺ influx and efflux in rat adrenal glomerulosa cells stimulated by Ang II or K⁺ and observed the time course of the inhibition of the two phases of response, using a superfusion system of adrenal glomerulosa cells.

Materials and Methods

Synthetic rat ANF (28 amino acids) was purchased from Peninsula Laboratories (Belmont, CA, USA). Synthetic [Asp¹,Leu⁵]Ang II and bovine serum albumin were obtained from Sigma Chemical (St. Louis, MO, USA), collagenase from Worthington Diagnostics Division (Millipore, Freehold, NJ, USA), ⁴⁴CaCl₂ from Amersham (Arlington Height, IL, USA), Medium 199 with Hanks' salts from Gibco (Grand Island, NY, USA), and aldosterone radioimmunoassay kit from Diagnostic Products (Los Angeles, CA, USA).
Preparation of Adrenal Glomerulosa Cells

Female Sprague-Dawley rats (weight, 180–220 g; Harlan, Indianapolis, IN, USA) maintained on a regular sodium diet (Wayne Lab Blox, Allied Mills, Chicago, IL, USA) were used for the experiments. The rats were killed by decapitation, and the capsular portions of the adrenal glands were separated by incising the capsule and squeezing the decapsular portions. Minced capsular tissues were incubated with collagenase (2 mg/ml) in Medium 199 with Hanks’ salts for 30 minutes at 37°C under an O2 atmosphere and dispersed by repeated agitation using a pipette. Medium 199 with Hanks’ salts contained 1.25 mM Ca2+, 3.5 mM K+ , 5.5 mM glucose, and 0.2% bovine serum albumin and was adjusted to pH 7.4. The cell suspensions were filtered through a nylon mesh (70 μm pore size) and centrifuged at 100 g for 15 minutes. The cell pellets were resuspended in fresh Medium 199 and used for the Ca2+ efflux study and the superfusion study.

For the Ca2+ influx study, the cells were loaded onto a 0 to 60% linear gradient of colloidal silica (Percoll, Pharmacia, Piscataway, NJ, USA) solution in Medium 199 and centrifuged at 800 g for 15 minutes to remove contaminating red blood cells, fasciculata cells, and damaged cells. A band containing glomerulosa cells was obtained above a band of red blood cells and beneath the layers of fasciculata cells and of damaged cells or cell debris.

The separated glomerulosa cells were filtered through nylon mesh to remove lipid lumps produced by the cells. After three washings, the cells were reconstituted with fresh media containing 2% bovine serum albumin for the Ca2+ influx study. These glomerulosa cell suspensions were contaminated with 1 to 3% fasciculata cells, but were almost free of red blood cells and damaged cells. For the Ca2+ influx study with K+ stimulation, Krebs-Ringer bicarbonate glucose buffer (KRBGA), in the same concentrations of Ca2+, K+, glucose, and bovine serum albumin, was used. In this case all incubations were done under 95% O2, 5% CO2, to maintain pH 7.4. The basal Ca2+ influx rate and the K+-stimulated influx rate obtained with KRBGA were not different from those obtained with Medium 199 (as described in Results).

Ca2+ Influx Study

The Ca2+ influx was measured according to the method previously described by Mauger et al.14 and Kojima et al.12 In brief, incubation was started by adding 500 μl of cell suspension (1.5–3 × 106 cells/ml) to 2 ml of Medium 199 and centrifuged at 100 g for 15 minutes. The cell pellet was resuspended in fresh Medium 199 for 10 minutes. The cell suspension (1–1.5 × 106 cells/ml) was applied to the column containing 0.5 ml of Sephadex G-15. The column was placed in a water bath at 37°C and perfused at a flow rate of 0.5 ml of media per minute. Two-minute (1 ml) fractions were collected for the measurement of 45Ca2+.

Ca2+ Efflux Study

For the Ca2+ efflux study, the cells were loaded onto a 0 to 60% linear gradient of colloidal silica (Percoll, Pharmacia, Piscataway, NJ, USA) solution in Medium 199 and centrifuged at 800 g for 15 minutes to remove contaminating red blood cells, fasciculata cells, and damaged cells. A band containing glomerulosa cells was obtained above a band of red blood cells and beneath the layers of fasciculata cells and of damaged cells or cell debris.

The separated glomerulosa cells were filtered through nylon mesh to remove lipid lumps produced by the cells. After three washings, the cells were reconstituted with fresh media containing 2% bovine serum albumin for the Ca2+ efflux study. These glomerulosa cell suspensions were contaminated with 1 to 3% fasciculata cells, but were almost free of red blood cells and damaged cells. For the Ca2+ efflux study with K+ stimulation, Krebs-Ringer bicarbonate glucose buffer (KRBGA), in the same concentrations of Ca2+, K+, glucose, and bovine serum albumin, was used. In this case all incubations were done under 95% O2, 5% CO2, to maintain pH 7.4. The basal Ca2+ influx rate and the K+-stimulated efflux rate obtained with KRBGA were not different from those obtained with Medium 199 (as described in Results).

Aldosterone Production in the Superfusion System of Dispersed Adrenal Glomerulosa Cells

The same procedures were followed as described for the Ca2+ efflux study, except that 500 μl of cell suspension (1–1.5 × 106 cells/ml) was applied to the column without 18C2+ prelabeling and that 4-minute fractions (1 ml each) were collected at a flow rate of 0.25 ml/min after a 30-minute static incubation and a 30-minute washout perfusion. To observe the effect of
ANF on the initial phase of aldosterone response to Ang II or K⁺, ANF was added to the cells 10 minutes before the start of the stimulation of Ang II (10⁻⁹ M) or K⁺ (12 mM) and the infusion was continued during the 30-minute stimulation. In addition, ANF was added 20 minutes after the start of the 50-minute stimulation and continued for 30 minutes to see the effect of ANF on the sustained phase of the response. Aldosterone in each fraction of perfusate was measured without extraction using the radioimmunoassay kit.

**Statistical Evaluation**

Results are shown as the means ± SE. Statistical analysis was done with analysis of variance, the multiple comparison method by Dunnett,¹⁶ and the Tukey-Kramer method.

**Results**

**Effect of ANF on Ca²⁺ Influx Stimulated by K⁺ or Ang II**

Figure 1 shows ⁴³Ca²⁺ uptake into purified rat adrenal glomerulosa cells. ⁴⁵Ca²⁺ uptake was stimulated significantly by the increase in K⁺ concentration (from 3.5 to 8 mM) or Ang II (10⁻⁸ M) as compared with basal uptake at every sampling time (15–105 seconds). However, the stimulation of Ca²⁺ uptake was not inhibited by ANF (10⁻⁸ M) at any sampling time. The Ca²⁺ influx rate was calculated from the regression lines obtained in each experiment (Tables 1 and 2). Table 1 shows the effect of ANF and verapamil on the Ca²⁺ influx rate in adrenal glomerulosa cells stimulated by K⁺ using KRBGA buffer. K⁺ significantly stimulated the Ca²⁺ influx rate (0.91 ± 0.10 vs 0.42 ± 0.04 nmol/min/10⁶ cells; p<0.01). ANF did not block the Ca²⁺ influx response to K⁺ (0.99 ± 0.18 nmol/min/10⁶ cells), while verapamil blocked the Ca²⁺ influx stimulated by K⁺ (0.50 ± 0.12 nmol/min/10⁶ cells). Our preliminary experiments showed that the aldosterone response to Ang II stimulation is better in Medium 199 than in KRBGA buffer. Therefore, we used Medium 199 instead of KRBGA buffer to evaluate the effect of ANF on Ca²⁺ influx stimulated by Ang II.

Basal and K⁺-stimulated Ca²⁺ influx rates in Medium 199 were the same as in KRBGA buffer (see Table 2). As shown in Table 2, two different concentrations of Ang II (10⁻⁹ and 10⁻⁸ M) significantly stimulated Ca²⁺ influx (0.62 ± 0.02 and 0.71 ± 0.09, respectively, vs 0.44 ± 0.03 nmol/min/10⁶ cells; p<0.05). However, the presence of ANF (10⁻⁸ M) did not change Ca²⁺ influx stimulated by the two concentrations of Ang II (10⁻⁹ M Ang II + ANF, 0.62 ± 0.06; 10⁻⁸ M Ang II + ANF, 0.69 ± 0.14 nmol/min/10⁶ cells).

**Effect of ANF on Ca²⁺ Efflux Stimulated by K⁺ or Ang II**

Figure 2 shows ⁴³Ca²⁺ release from ⁴³Ca²⁺-preloaded cells into each fraction of perfusate during K⁺ stimulation in a typical experiment. An increase in K⁺ in the media (from 3.5 to 12 mM) elicited Ca²⁺ release from the cells. In two pilot experiments, verapamil (2 x 10⁻⁵ M) reduced the Ca²⁺ efflux in response to K⁺ by 70%, whereas ANF (10⁻⁸ M) did not change it. The rate of Ca²⁺ efflux expressed as FER was in-

Increased by adding K⁺, but it was not modified in the presence of ANF, as shown in Figure 3 (top panel; peak of FER; K⁺ alone, 1.374 ± 0.051; K⁺ + ANF, 1.388 ± 0.011). Figure 3 (bottom panel) demonstrates that ANF did not reduce the increase in FER elicited by Ang II (peak of FER: Ang II alone, 1.432 ± 0.066; Ang II + ANF, 1.394 ± 0.017). Both figures show that ANF did not have any significant effect on basal Ca²⁺ efflux before the stimulants were added.

Aldosterone Production in the Superfusion System of Dispersed Adrenal Glomerulosa Cells

Figures 4 and 5 demonstrate the time course of aldosterone release from the dispersed adrenal glomerulosa cells in each column. Both 12 mM K⁺ and 10⁻⁹ M Ang II markedly stimulated aldosterone production. ANF (10⁻⁸ M), which had been added 10 minutes beforehand, inhibited the initial phase of the aldosterone response (see Figure 4). The values of aldosterone production after stimulation by K⁺ or Ang II in the presence or absence of ANF are shown in Table 3. Figure 5 demonstrates that the addition of ANF 20 minutes after the start of the stimulation with either K⁺ or Ang II caused a rapid fall in the sustained phase of aldosterone production, indicating that ANF inhibits both phases of the aldosterone response.

Discussion

ANF inhibits aldosterone production in adrenal glomerulosa cells stimulated by the three major regulators (i.e., Ang II, K⁺, and ACTH) in vitro. ANF also inhibits the increase in plasma aldosterone level in response to the administration of ANG II or KCl in vivo. Recent studies have shown that the three major regulators of aldosterone production act on adrenal cells through the intracellular calcium messenger system. In the case of Ang II stimulation, initial major changes are an increase of Ca²⁺ influx across plasma membrane and hydrolysis of phosphatidylinositol 4,5-bisphosphate, which gives rise to diacylglycerol and inositol 1,4,5-triphosphate. Inositol 1,4,5-triphosphate stimulates the release of Ca²⁺ from an intracellular store, causing a transient rise in the calcium concentration in the cell cytosol. This rise in the cytosolic Ca²⁺ leads to the activation of calmodulin-dependent processes responsible for the initiation of the aldosterone secretory response. One of the calcium-dependent enzymes that is activated by the cytosolic Ca²⁺ is the plasma membrane calcium pump. Its activation causes an increase in the rate of Ca²⁺ efflux from the cells. The rise in diacylglycerol content of the plasma membrane, along with the transient rise in the...
Ca\(^{2+}\) concentration, brings about the activation of C-kinase. Once activated, this enzyme remains in its Ca\(^{2+}\)-sensitive state and regulates the sustained phase of cellular response. In the case of K\(^{+}\) or ACTH stimulation, an increase in Ca\(^{2+}\) influx and in cyclic adenosine 3',5'-monophosphate (cAMP) content are the initial major changes. These activate calmodulin-dependent enzymes and A-kinase, respectively. A-kinase is the enzyme responsible for the sustained phase of the response. The difference between the actions of K\(^{+}\) and ACTH is thought to be in the relative magnitude of the two messengers, Ca\(^{2+}\) influx being the predominant one with K\(^{+}\) and cAMP with ACTH. One group reported that ANF did not alter the inhibitory effect of Ang II on Ca\(^{2+}\) fluxes in bovine glomerulosa cells measuring \(^{45}\)Ca\(^{2+}\) uptake during the first 15 minutes.\(^\text{18}\) In their experimental system Ang II exerted an inhibitory effect on Ca\(^{2+}\) fluxes instead of a stimulatory effect. They did not study Ca\(^{2+}\) influx and efflux separately in the early phase of the response. In the present investigation, we studied separately the effect of ANF on Ca\(^{2+}\) influx and efflux in rat glomerulosa cells after Ang II and K\(^{+}\) stimulation.

The superfusion system of dispersed glomerulosa cells demonstrated that the aldosterone response to Ang II, K\(^{+}\), or ANF is greater than in the static incubation system (see Table 3). For example, the increase in aldosterone production in response to Ang II was approximately 100-fold, while it is only twofold to sixfold in the static incubation system.\(^\text{14}\) The difference

Values show means ± SE in three consecutive fractions during 56 to 68 minutes of three experiments.

Aldosterone in each fraction of perfusate (1 ml/4 min) was measured. The administration of 10\(^{-8}\) ANF and the two stimulators (12 mM K\(^{+}\) or 10\(^{-9}\) Ang II) started at 30 and 40 minutes, respectively.

\(*p<0.05\), compared with basal values.

\(†p<0.05\), compared with Ang II values.

\(‡p<0.05\), compared with K\(^{+}\) values.
may be explained by the fact that in the superfusion system fresh media containing Ang II is always being supplied to cells; Ang II is easily destroyed during incubation with cells. Another possibility is that toxic metabolites from the cells and breakdown products in the media that might interfere with the cellular metabolism are continuously washed out. As shown in Figures 4 and 5, the aldosterone response occurred immediately after the administration of Ang II or K+, and the high output was maintained during the stimulation. ANF inhibited both the initial and the sustained phases of the response.

In the Ca2+ influx study, two different concentrations of Ang II (10-9 and 10-8 M) and 8 mM K+ significantly increased Ca2+ influx. Verapamil (2 x 10-5 M) blocked the increase in Ca2+ influx stimulated by K+, which demonstrates that our experimental system could detect the specific effect of the Ca2+ channel blocker. In this system, ANF did not alter the Ca2+ influx rate stimulated by K+ or Ang II. These findings conflict with the result reported recently by Chartier and Schiffrin. They reported that Ca2+ influx stimulated by Ang II, ACTH, K+, or the dihydro- pyridine Bay k8644 was decreased by ANF (10-9 M), using rat adrenal capsular cells. In our experiments the adrenal capsular cell suspension contained a large number of red blood cells, damaged cells, and cell debris, so in order to purify the glomerulosa cells and remove potential interference by the other cells it was necessary to use a Percoll gradient, as described by Kojima et al. Chartier and Schiffrin did not purify their adrenal capsular cell suspension, and that may have led to nonspecific effects caused by the other cells or damaged cells. In our experiment the basal influx rate was 0.44 ± 0.03 nmol/min/106 cells in Medium 199. These values are not different from those (0.39-0.75 nmol/min/106 cells) of Mauger et al. using rat liver cells, as calculated from their results, but they are one order of magnitude higher than those reported by Chartier and Schiffrin (0.053-0.056 nmol/min/106 cells).

In the Ca2+ efflux study, the FER stimulated by K+ was similar to the FER (1.5) in the experiment performed by Kojima et al. using bovine adrenal cells. On the other hand, the increase in FER caused by Ang II was lower than in their data (3.5-fold). This discrepancy could be attributed to the species differences as they have described between bovine cells and porcine cells. ANF did not modify Ca2+ FER in our experiment.

The results in the Ca2+ influx and efflux experiments indicate that the inhibitory effect of ANF on aldosterone production is not caused by interference with the calcium messenger signal and that the inhibitory effect occurs distal to the generation of calcium signal. Recently, Capponi et al., using the quin 2 method, reported that ANF did not affect the transient changes in cytosolic free calcium triggered by Ang II in bovine adrenal glomerulosa cells and cultured rat aortic smooth muscle cells, nor did it alter resting cytosolic free calcium levels. Similarly, Aguilera et al., using quin 2 in rat adrenal glomerulosa cells, and Apfeldorf et al., using aequorin in bovine adrenal glomerulosa cells, concluded that ANF does not affect cytosolic calcium. Their results are consistent with ours. On the other hand, Hassid reported that, in culture smooth vascular muscle cells, ANF decreased basal cytosolic free calcium level as well as the sustained increase following the peak after Ang II stimulation. The reason for the discrepancy between these results and those of Capponi et al. is not clear.

In conclusion, our results indicate that ANF does not affect Ca2+ influx or efflux in rat adrenal glomerulosa cells and that the inhibitory effect of ANF must occur after the generation of the Ca2+ signal in the cells.
