Abstract N^\text{O},N^\text{G}-dimethyl-L-arginine (ADMA) is an endogenously synthesized nitric oxide (NO) synthase inhibitor which has potent pressor/vasoconstrictor effects. Dimethylargininase metabolizes ADMA to L-citrulline and plays a key role in determining the in vivo levels of ADMA. To investigate the role of ADMA in the pathogenesis of hypertension, we measured 24-hour urinary excretion of ADMA (UADMA) and nitrate/nitrite (NOx) in Dahl salt-sensitive hypertensive rats and spontaneously hypertensive rats (SHR). In Dahl salt-resistant rats, high-salt diet (8% NaCl) did not increase blood pressure or increased urinary NOx (P<0.01) without changes in UADMA compared with low-salt diet (0.1% NaCl). In contrast, in Dahl salt-sensitive rats, high-salt diet increased blood pressure (P<0.01), did not change urinary NOx excretion, and increased UADMA (P<0.01). There was a significant (r=65, P<0.01) correlation between UADMA and the level of blood pressure in Dahl salt-sensitive rats. Plasma levels of NOx and ADMA and renal dimethylarginine content were comparable among them. These results may suggest that in Dahl salt-resistant rats, blood pressure is kept constant during high-salt intake, possibly due to the compensatory increased production of NO, and that in Dahl salt-sensitive rats, high-salt intake increases the production of ADMA, attenuates the compensatory increases in NO, and increases blood pressure. These results also suggest that the systemic production of ADMA is not dependent on renal dimethylarginase. SHR had significantly greater urinary NOx excretion (P<0.05) and smaller UADMA than Wistar-Kyoto rats (P<0.05), and ADMA was inversely correlated with their mean arterial pressure (r=64, P<0.05). In conclusion, ADMA, independently of the renal dimethylarginase content, may play a role in the pathogenesis in Dahl salt-sensitive hypertensive rats but not in SHR (Hypertension. 1997;29[part 2]:242-247.)

Nitric oxide is a mediator involved in the regulation of vascular tone, neurotransmission, and host defense. NO is synthesized from L-arginine, and defects in its synthetic pathway have been implicated in several diseases. Attempts to evaluate a role of NO in experimental hypertension have been extensively performed, however, the results of these studies have been highly divergent, depending on animal models and vascular beds examined. In salt-sensitive hypertension, abnormalities of the L-arginine–NO pathway have been demonstrated. Increases in dietary salt raised the NO production (estimated from urinary cGMP) in salt-resistant Dahl/Rapp rats but not in salt-sensitive rats. Parenteral or oral administration of L-arginine abrogated salt-sensitive hypertension and improved pressure natriuresis. These studies suggest that the salt-sensitive Dahl rat possesses a unique defect in the production of NO that manifests as hypertension with high-salt diet and is corrected by administration of the biological substrate for NO synthesis. In contrast to the Dahl rat, L-arginine does not affect the development of hypertension in SHR. Acute studies using NO synthesis inhibitors intravenously have suggested that the NO production is preserved in SHR. Furthermore, recent evidence demonstrated the increased but not decreased production of NO in the heart and aorta of SHR.

The synthesis of NO can be inhibited experimentally by some analogues of arginine including L-NMMA and ADMA, both of which have equally potent vasoconstrictor and pressor actions. Acute administration of ADMA into guinea pigs and rats causes blood pressure elevation partly via elevation of total peripheral resistance. In humans, intra-arterial administration of ADMA lowers forearm blood flow. Although both L-NMMA and ADMA are synthesized and metabolized endogenously, the plasma concentration of dimethylarginine is ten times greater than that of L-NMMA. Since studies in animals suggest that the kidney may be involved in the excretion and metabolism of ADMA, abnormalities of the ADMA production or elimination have been reported in human kidney diseases. Although recent evidence demonstrated high accumulation of ADMA in plasma from hypercholesterolemic animals and in balloon-injured vessels, the role of this endogenous NO synthase inhibitor in the pathogenesis of hypertension has not been elucidated at all.

Accordingly, we hypothesized that endogenous ADMA may play a role in salt-sensitive hypertension by competitive inhibition of NO synthesis. To test this hypothesis, urinary and plasma ADMA and NOx were evaluated in Dahl rats on different salt intakes. We also measured urinary and plasma ADMA in SHR as a model of salt-sensitive, NO-independent hypertension to exclude the

Nitric oxide is a mediator involved in the regulation of vascular tone, neurotransmission, and host defense. NO is synthesized from L-arginine, and defects in its synthetic pathway have been implicated in several diseases. Attempts to evaluate a role of NO in experimental hypertension have been extensively performed, however, the results of these studies have been highly divergent, depending on animal models and vascular beds examined. In salt-sensitive hypertension, abnormalities of the L-arginine–NO pathway have been demonstrated. Increases in dietary salt raised the NO production (estimated from urinary cGMP) in salt-resistant Dahl/Rapp rats but not in salt-sensitive rats. Parenteral or oral administration of L-arginine abrogated salt-sensitive hypertension and improved pressure natriuresis. These studies suggest that the salt-sensitive Dahl rat possesses a unique defect in the production of NO that manifests as hypertension with high-salt diet and is corrected by administration of the biological substrate for NO synthesis. In contrast to the Dahl rat, L-arginine does not affect the development of hypertension in SHR. Acute studies using NO synthesis inhibitors intravenously have suggested that the NO production is preserved in SHR. Furthermore, recent evidence demonstrated the increased but not decreased production of NO in the heart and aorta of SHR.

The synthesis of NO can be inhibited experimentally by some analogues of arginine including L-NMMA and ADMA, both of which have equally potent vasoconstrictor and pressor actions. Acute administration of ADMA into guinea pigs and rats causes blood pressure elevation partly via elevation of total peripheral resistance. In humans, intra-arterial administration of ADMA lowers forearm blood flow. Although both L-NMMA and ADMA are synthesized and metabolized endogenously, the plasma concentration of dimethylarginine is ten times greater than that of L-NMMA. Since studies in animals suggest that the kidney may be involved in the excretion and metabolism of ADMA, abnormalities of the ADMA production or elimination have been reported in human kidney diseases. Although recent evidence demonstrated high accumulation of ADMA in plasma from hypercholesterolemic animals and in balloon-injured vessels, the role of this endogenous NO synthase inhibitor in the pathogenesis of hypertension has not been elucidated at all.

Accordingly, we hypothesized that endogenous ADMA may play a role in salt-sensitive hypertension by competitive inhibition of NO synthesis. To test this hypothesis, urinary and plasma ADMA and NOx were evaluated in Dahl rats on different salt intakes. We also measured urinary and plasma ADMA in SHR as a model of salt-sensitive, NO-independent hypertension to exclude the
possibility that changes in ADMA may be merely an epiphenomenon secondary to blood pressure elevation

Methods

Animals

Dahl/Rapp salt-sensitive rats (DS) and salt-resistant rats (DR) at 7 weeks of age (Saywa, Japan) were placed on either 0.3% or 8% NaCl diet (Oriental Kohbo, Japan) for 1 week (n=8 to 10) SHR and WKY at 7 weeks old (6 each, Charles River Japan, Kanagawa) were fed normal rat chow (CE-2, Clea Japan, Tokyo), which consisted of 110 mmol sodium, 280 mmol potassium, and 15.5 g arginine per kilogram. Throughout the study period, animals were housed in a room at constant temperature (25 ± 1°C) and humidity (60 ± 5%). The room was lighted automatically from 7 a.m. to 7 p.m. Rats were provided free access to water and rat chow. Animal care and treatment were conducted in conformity with institutional guidelines that are in compliance with international laws and policies (EEC Council Directive 86/609, OJL 358, December 1987, NIH Guide for the Care and Use of Laboratory Animals, NIH publication No. 85-23, 1985).

Experimental Protocol

DS or DR fed high- or low-salt diet and SHR or WKY fed normal diet for 1 week were weighed and housed over 24 hours in individual metabolic cages to measure water intake, the consumption of rat chow, urine volume, and 24-hour urinary excretion of NOx and ADMA. The metabolic study was performed for only 1 day. After the metabolic experiment, rats were anesthetized with pentobarbital (50 mg/kg), and a catheter (PE-10 connected to PE-50) was passed into the lower abdominal aorta via the right femoral artery to measure MAP directly for 1 hour (model TP-101T, Nihon Koden). Reported pressures represent the average MAP during the last 15 minutes of the recording period. After measurements of MAP, blood was withdrawn for analysis of plasma NOx and ADMA, and all rats were killed immediately after removal, kidneys were frozen in liquid nitrogen for Western blot analysis.

Chemical Analysis

Immediately after sampling, blood was centrifuged in plain tubes without heparin for NOx measurement and in heparinized tubes for ADMA measurement. Urine and plasma samples were stored at −85°C until analysis. The frozen kidneys were rapidly minced and placed on ice in 9 volumes of 10 mmol/L sodium phosphate buffer, pH 7.0, containing 1 mmol/L 2-mercaptoethanol, trypsin inhibitor (10 mg/L), leupeptin (10 mg/L), pepstatin (10 mg/L), and antipain (10 mg/L), using a Polytron homogenizer. After centrifugation at 10,000 g for 40 minutes, the supernatant was stored at −85°C until analysis. Urine sodium was determined by flame photometer (No 710, Hitachi).

Analysis of NOx and ADMA

NOx were determined by a colorimetric method using the Griess reagent (Wako). Urinary NOx and ADMA excretion were calculated as products of the 24-hour urine volume and urinary NOx and ADMA concentration, respectively.

Results

Hemodynamics and Urinary Sodium Excretion

MAP of DS fed high salt diet (DSH) was significantly higher than that of DS fed low-salt diet (DSL) (Fig 1, P<0.01). MAP was similar between DR fed high-salt diet (DRH) and DR fed low-salt diet (DRL). MAP was significantly higher in SHR than in WKY (Fig 2, P<0.005). Although SIIR had significantly higher heart rate compared with WKY (340±14 versus 290±9 bpm, P<0.05), there were no significant differences in heart rate among Dahl rats (DSH, 316±13, DSL, 342±7, DRH, 341±13, and DRL, 314±15 bpm, NS) in Dahl rats fed high-salt diet, urinary sodium excretion was significantly (P<0.01) greater than in rats fed low-salt diet, although there was no significant difference in urinary sodium excretion between salt-sensitive and -resistant rats on either high-
NOx and ADMA

DR fed high-salt diet had greater urinary NOx excretion than DR fed low-salt diet (Fig 1, P<.01). However, in DS, there was no significant difference in urinary NOx excretion between high-salt and low-salt diet (Fig 1, NS). The plasma NOx level was similar among groups (DSH, 10.0±0.7; DSL, 9.5±0.5; DRH, 10.2±0.5; and DRL, 9.6±0.7 μmol/L, NS). Urinary ADMA excretion was significantly greater in DS fed high-salt diet than in DS fed low-salt diet (Fig 1, P<.01) and was similar between the two groups of DR rats. The plasma ADMA level was similar among groups (DSH, 0.73±0.03; DSL, 0.66±0.03; DRH, 0.69±0.03; and DRL, 0.67±0.03 pmol/L; NS).

Urinary NOx excretion was significantly greater in SHR than in WKY (Fig 2, P<.05), although there was no difference in the plasma NOx concentration (SHR, 14.4±1.2; WKY, 13.4±2.5 μmol/L; NS). There was no difference in the plasma ADMA concentration (SHR, 0.62±0.03 versus WKY, 0.62±0.03 μmol/L; NS); urinary ADMA excretion, however, was significantly smaller in SHR than in WKY (Fig 2, P<.05).

Correlation Between MAP and ADMA

In DS, the amount of urinary ADMA excretion was positively correlated with MAP (r=.65, P<.01) (Fig 3a), whereas in SHR and WKY the amount of urinary ADMA excretion was inversely correlated with MAP (r=-.64, P<.05; Fig 3b).

Dimethylargininase Immunoblot Analysis

Fig 4 shows Western blot analysis of dimethylargininase in kidney extracts. Either between SHR and WKY or among Dahl rats on different diets, there were no significant differences in protein levels of dimethylargininase in the kidney. Accordingly, laser densitometric scan of Western blots revealed no differences between SHR and WKY (SHR 112±12% versus WKY 100±0%; and among four groups of Dahl rats (DSH, 114±14%; DSL, 144±23%; DRH, 118±20%; and DRL, 100±0%).

Dimethylargininase Immunohistochemical Analysis

Fig 5 shows representative photomicrographs of dimethylargininase immunohistochemical staining in kidney of DS fed high-salt diet (top) and SHR (bottom). Dimethylargininase was localized in the luminal side of tubular epithelium, whereas no immunoreactivity was detected in the vasculature and glomeruli. These results were similar among strains and between low- and high-salt diet (data not shown).

Discussion

The purpose of this study was to examine the role of ADMA, an endogenous NO synthase inhibitor, in experimental hypertension. High-salt diet raised blood pressure...
with increases in urinary ADMA excretion in DS. There was a significant correlation between the amount of ADMA excretion and arterial pressure. Because high-salt diet increased urinary NOx excretion in DR but not in DS, our results may be interpreted to suggest that the NO production is compensatorily increased during high-salt intake to attenuate blood pressure elevation in DR, whereas the increased production of ADMA during high-salt intake elevates blood pressure by inhibiting the compensatory increases in the NO production in DS. In contrast to Dahl rats, high blood pressure in SHR was associated with increased urinary NOx excretion and decreased ADMA excretion compared with WKY. Our results suggest that ADMA may play a role in the pathogenesis of hypertension in DS but not in SHR and that the increase in ADMA in DS during high-salt intake may not be just an epiphenomenon of hypertension.

The in vivo activity of NO cannot be directly monitored because NO is very unstable and rapidly metabolized by oxidation initially to nitrite (NO2) and ultimately to the stable end product, nitrate (NO3). We therefore evaluated the 24-hour urinary NOx production as an index of the NO production in this study. Although urinary NOx excretion has been considered to reflect the systemic NO production, dietary intake of NOx and tubular reabsorption predominantly affect the NOx production. Because the 24-hour consumption of rat chow measured simultaneously with the urine collection was similar among rat groups (data not shown), the greater NOx excretion in DR on high-salt diet was not due to the greater NOx intake. It is possible that the renal tubular handling of NOx among Dahl rats is different and may have caused greater excretion of NOx in DR on high-salt diet. The recent study from the laboratory of Dr Baylis (Sütö et al) has shown that NOx is reabsorbed extensively in the proximal tubule and that inhibition of proximal reabsorption leads to an increase in urinary NOx. They suggested that measurements of acute changes in urinary NOx should be interpreted cautiously, since it may reflect altered tubular handling of NOx rather than the changes in the systemic and/or renal NO production. However, our studies were conducted in the chronic setting of 1 week, and the changes in the tubular handling were less likely to account for our results, although the possibility remains.

It has been reported that high-salt intake induces NO synthase in normotensive rats, and functional defects of such adaptive response have been suggested as a pathogenesis of salt-sensitive hypertension. Indeed, Chen and Sanders reported that the increase in urinary cGMP excretion in response to high-salt diet was significantly lower in Dahl/Rapp salt-sensitive rats, suggesting impaired NO synthesis as a maladaptation to high-salt stress. In accordance with the previous study, we demonstrated that high-salt diet increased urinary NOx excretion in normotensive Dahl salt-resistant rats, whereas salt-sensitive hypertensive rats did not show any change in NOx in responses to high-salt diet. Thus, our results also suggest the impaired NO production in DS on high-salt intake. The mechanisms of this impaired NO synthesis of salt-sensitive rats on high-salt diet are unknown. Because ADMA is an endogenous L-arginine analogue that has potent vasoconstrictor/pressor effects by inhibiting NO synthesis and because it has been demonstrated that chronic L-arginine administration abrogates salt-sensitive hypertension and improves pressure natriuresis, we thought that endogenous ADMA may play a role in salt-sensitive hypertension by competitive inhibition of NO synthesis. Indeed, in contrast to NOx, urinary ADMA excretion increased in only salt-sensitive rats fed high-salt diet but not in salt-resistant rats. Furthermore, the amount of urinary excretion of the endogenous NO synthase inhibitor was positively correlated with blood pressure in salt-sensitive rats. The increase in urinary ADMA excretion in DS on high-salt intake is not likely to be a secondary phenomenon in response to blood pressure elevation, because SHR had lower urinary ADMA excretion than WKY. Although we have not
mechanisms by which high-salt intake increased urinary ADMA excretion are not clarified in this study, but several possibilities are considered. Although the metabolic pathway of ADMA in physiological conditions has been extensively investigated by the laboratories of Ogawa and of Vallance, we have little information regarding the altered metabolism in pathological conditions. ADMA is produced in several organs, released into blood, and excreted from the kidney. However, the plasma level and urinary excretion are mainly determined by the renal production and excretory capacity of ADMA. It is unlikely that the excretory capacity of ADMA from the kidney was augmented in DS on high-salt intake because the plasma level of ADMA was similar among strains. It is possible that greater urinary ADMA excretion may reflect augmented renal production of ADMA in DS, since our results, as well as those of others, demonstrated the impaired renal production of NO in salt-sensitive rats, which was reversed by L-arginine supplement. Since dimethylargininase has been considered as a key limiting enzyme of ADMA and reported to distribute dominantly in the kidney, we conducted Western blot and immunohistochemical analyses of this enzyme in the kidney to examine whether dimethylargininase in the kidney accounts for the augmented urinary ADMA excretion in DS on high-salt intake. Both protein levels and immunoreactivities of dimethylargininase were similar among Dahl rats and similar between SHR and WKY. Thus, it is unlikely that the renal degradation of ADMA was attenuated in DS on high-salt intake. Finally, it is also possible that the increased urinary excretion was due to the systemic overproduction of ADMA. Dimethylargininase is localized not only in the kidney but also in the pancreas and...
Liver. High-salt intake may have inhibited enzymatic activity in such organs, resulting in the systemic overproduction of ADMA. Therefore, measurements of hepatic or pancreatic levels of this enzyme would be helpful to reveal the source of the increase in ADMA. Further experiments will be needed.

In the present study, Dahl rats were fed high- or low-salt diet only for 1 week. Nonetheless, high-salt-fed DS showed significant blood pressure elevation. Chronic high-salt exposure to salt-sensitive rats is known to cause vascular damage, which may affect NO production non-specifically secondary to hypertension. To avoid this possibility, we fed them for only 1 week in this study. The longer feeding in Dahl rats may have produced different results for NOx and ADMA. Our results may suggest that ADMA is involved in the development of salt-sensitive hypertension. However, additional experiments in which measurements are made of MAP and NOx excretion during chronic administrations of ADMA or of an inhibitor of dimethylargininase in Dahl rats during high-salt intake may be necessary to verify our conclusion. These studies should be performed in the future.

In summary, DS fed high-salt diet had significantly higher blood pressure, lower NO production, and greater excretion of endogenous NO synthase inhibitor than DSS fed low-salt diet. Urinary ADMA excretion was significantly correlated with arterial pressure in DS SHR had excretion of endogenous NO synthase inhibitor than DSS. The results for NOx and ADMA may suggest that specific NOx and ADMA results for NOx and ADMA. Our results may suggest that ADMA is involved in the development of salt-sensitive hypertension. However, additional experiments in which measurements are made of MAP and NOx excretion during chronic administrations of ADMA or of an inhibitor of dimethylargininase in Dahl rats during high-salt intake may be necessary to verify our conclusion. These studies should be performed in the future.
