Chronic AT$_1$ Receptor Blockade Alters Aortic Nerve Activity in Hypertension

Claudia M. dos Santos, Edson D. Moreira, Eduardo M. Krieger, Lisete C. Michelini

Abstract—In the chronic phase of coarctation hypertension (CH) we have shown both reduction in baroreceptor sensitivity (Hypertension. 1992;19[ suppl II]:II-198–II-201.) and normalization of the depressed baroreceptor reflex control of heart rate, even with the persistence of hypertension in losartan-treated animals (Am J Physiol. 1995;269:H812–H818). In the present study we analyzed the effects of angiotensin II blockade on afferent aortic nerve activity of CH and sham-operated groups treated chronically with vehicle or losartan (10 mg/kg per day PO). CH was induced by subdiaphragmatic aortic coarctation, and the treatments lasted 8 days (4 control and 4 experimental days). Aortic pressure (conscious rats) and aortic nerve activity simultaneous to pressure (anesthetized rats) were recorded on the fourth day of the experimental period. Losartan-treated rats showed reduced tail pressure (104±3 versus 117±3 mm Hg in the vehicle group). In both groups, aortic coarctation caused a significant increase in pressure (25% and 28%, respectively) and a depression of the aortic nerve activity/presure relationship when compared with sham-operated coarcted animals. In the physiological range of pressure changes, the depression was significantly smaller after losartan treatment (3.30±0.33 versus 2.18±0.37%/mm Hg in the losartan- and vehicle-treated CH groups, respectively, versus 5.05±0.33%/mm Hg in the sham-operated vehicle-treated group). Angiotensin type 1 (AT$_1$) receptor blockade was also accompanied by reduced variability of the afferent discharge. The data suggested that apart from its pressure effect, angiotensin II acts at AT$_1$ receptors to decrease the sensitivity of aortic afferents during physiological (±10 mm Hg) increases and decreases in pressure. Thus, angiotensin II may contribute to reductions of baroreceptor gain in chronic hypertension. (Hypertension. 1998;31:973-977.)

Key Words: baroreceptors ■ angiotensin II ■ receptors, angiotensin ■ blood pressure ■ losartan ■ hypertension, coarctation

The presence of an endogenous renin-angiotensin system in brain areas involved in cardiovascular regulation has been confirmed by several techniques. $^{1-3}$ Stimulation of high-affinity Ang II receptors $^{4-6}$ leads to a set of coordinated autonomic responses, yielding increases in blood pressure. $^{5-8}$ An important central action of Ang II is to modulate the baroreceptor reflex control of heart rate $^{9-14}$ and sympathetic tone, $^{9,15-18}$ determining for a given increase in blood pressure small compensatory reflex responses, thus contributing to the maintenance of hypertension.

In normotensive freely moving rats, we showed that subpressor doses of Ang II administered either into the nucleus tractus solitarii or into the fourth cerebral ventricle caused a marked blunting of the reflex bradycardia, with the bradycardic response being significantly improved by the blockade of endogenous Ang II with saralasin into the nucleus tractus solitarii. $^{19}$ We also showed that rats made hypertensive by subdiaphragmatic aortic constriction presented a significant depression of baroreceptor reflex control of heart rate, $^{20}$ which was completely normalized by chronic treatment with losartan even with the persistence of hypertension. $^{21}$ These observations indicate a specific effect of Ang II on the reflex control of heart rate other than that exerted on the blood pressure levels. These results, taken together with both the description of Ang II binding sites in all elements of the vagal afferent system (peripheral and central processes, nodose ganglion, brain stem nuclei containing terminal projections $^{22,23}$) and the observation of changes in Ang II receptor density in the solitarii-vagal complex after sinoaortic denervation, $^{24}$ prompted us to study whether Ang II modulates the afferent discharge of baroreceptors to the central nervous system. Therefore, the main objective of the present work was to determine the effects of chronic blockade of AT$_1$-Ang II receptors on the aortic nerve activity of coarcted hypertensive and normotensive control rats during the control period and during loading/unloading of aortic baroreceptors.

Methods

Male Wistar rats aged 3 to 4 months and weighing 200 to 300 g were used. During the study period, the rats were housed in individual cages on a 12-hour light/dark schedule and allowed free access to

food and water. All surgical procedures were approved by the ethics committees of our institutions. Two groups of rats were treated with vehicle orally (distilled water 0.001 mL/kg per day) or losartan (10 mg/kg per day). The treatments lasted 8 days: a control period of 4 days and an experimental period of 4 days.

After the control period, half of the animals in each group were subjected to CH and the other half were sham-coarcted (SHAM) and used as controls. CH, which induces hypertension of the upper part of systemic circulation was produced by partial subdiaphragmatic aortic constriction, according to a previously described technique.25,26 Briefly, under ether anesthesia, the rats were subjected to a median laparotomy, and the abdominal aorta was isolated just below the diaphragm, near the exit of the superior mesenteric artery. A cotton thread was used to constrict the aorta, the extent of narrowing being limited by a hypodermic needle (0.7 to 0.8 mm OD), according to the rat’s body weight. The needle was removed and the abdomen sutured. SHAM rats were submitted to the same surgical procedures, except for the narrowing of the abdominal aorta. All rats received 60 000 IU penicillin (Pentabiotic Veterinário, Fontoura-Wyeth).

Arterial pressure was measured by the tail-cuff technique using a Programmed Electro Sphygmomanometer (model PE-300, Narco Bio-Systems) for 2 weeks before treatments were started and after 3 to 4 days of losartan or vehicle therapy, immediately before CH or SHAM surgery. Pressure was measured directly with a Gould-Statham P23 Db transducer in conscious rats on day 4 of CH or SHAM. The right common carotid artery and jugular vein were cannulated at the end of day 3 to allow complete recovery from ether anesthesia. On day 4 after measurement of baseline pressure for 20 to 30 minutes, the rat was anesthetized with pentobarbital sodium (40 mg/kg IV), had a second artery (left brachial) cannulated, and was prepared for recording of aortic nerve activity. The procedure used to record whole nerve activity of aortic baroreceptors was similar to that used in previous studies.26,27 Aortic fibers of the left isolated aortic nerve or as a branch isolated from the left recurrent laryngeal nerve in the lower part of the neck were used. To assure the stability of the neural recording, a flexible, thin 5-mm gold electrode (0.05 mm in diameter) covered by a vinyl tube (0.50 mm in diameter) connected to a 100-mm platinum wire was placed around the nerve and carefully insulated with silicone rubber (Wacker Sil-Gel 604, Wacker Co). Arterial pressure (brachial) and aortic nerve activity were continuously monitored on an oscilloscope (5115 Storage Tektronix) and recorded on-line with a computer. The experimental protocol consisted of measurements of aortic nerve activity/pressure relationship at baseline pressure (control) and during rapid changes in pressure (10 to 15 seconds) induced by blood withdrawal (~0.08 mL/kg) and blood reinfusion (the volume withdrawn plus 0.04 to 0.05 mL/kg of blood from a donor rat, via the right carotid artery). The systolic pressure threshold (SPth) at which the aortic baroreceptors initiated firing, the saturation point (100% discharge), and the interval of pressure/nerve activity (range) were determined several times in each rat. To avoid influence of hysteresis, only the values obtained when pressure was changed from low to high levels were used to construct the aortic nerve function curves. We also recorded the afferent activity/pressure relationship at the physiological range of pressure fluctuations (±10 mm Hg from control value).

Table 1 presents the data from the average of two to three consistent measurements made during each experimental situation. To quantify the whole aortic nerve activity, the nerve traffic was filtered through a bandpass of 100 to 3000 Hz, amplified, full-wave rectified, and integrated with a time constant of 3.9 milliseconds. The integrator output provides the nerve activity for each cardiac cycle. The integrator output provides the nerve activity for each cardiac cycle. Pressure and nerve activity were sampled at 2000 Hz and subjected to analog-to-digital conversion (Codas, DataQ Instruments).

To compare baroreceptor activity curves (multifiber preparation), the afferent discharge was normalized, considering the saturation of the curve as 100%. Because neither saturation nor threshold were obtained in the recordings limited to a more physiological condition, these values were normalized considering the control discharge as 100% and were expressed as positive or negative percent changes at ±10 mm Hg. Results are presented as mean±SEM.

Blood Pressure Changes

In the control period, losartan-treated rats (4 days) were already hypotensive when compared with vehicle-treated animals (104±3 versus 117±3 mm Hg, tail pressure determinations, inset in Fig 1). Direct measurements of pressure in conscious rats (Fig 1) showed that CHLOS rats were hypertensive on day 4 of coarctation (a 28% increase; mean arterial pressure, 151±4 versus 118±3 mm Hg in SHAMLOS). In the chronic losartan-treated groups, baseline pressure was attenuated from the beginning, but CHLOS rats (mean arterial pressure, 130±4 mm Hg) were still hypertensive (a 25% increase) when compared with the SHAMLOS group (mean arterial pressure, 104±3 mm Hg).

Baroreceptor Function Curves

Pentobarbital anesthesia did not change the pressure levels presented by the four groups in the conscious state. The absolute afferent discharge of aortic nerve at the control period of CH and SHAM, treated with vehicle or losartan, is presented in the Table. For all groups, SPth values were similar to the respective baseline diastolic pressure.

Fig 2 illustrates and the Table summarizes the normalized afferent discharge/systolic pressure relationships for the four
groups of rats. Hypertension displaced the SPth to hypertensive levels (+8%) and reduced the slope of the curves, indicating afferent gain, which extended over a broader pressure interval (on average the range was increased by 66% CHVEH versus SHAM VEH). The aortic nerve activity curves of CHVEH also showed greater variability. Treatment with losartan did not change the afferent activity curve of SHAM animals (Fig 2, lower panel left) but only displaced the SPth to the left (from 109±4 to 96±4 mm Hg, Table) because of its pressure-lowering effect. Establishment of hypertension in losartan-treated rats also displaced the SPth to hypertensive levels (from 96±4 to 105±4 mm Hg), but the individual variability was smaller than that of the CHVEH group (Fig 2, lower panel right). The hypertension-induced decrease in the slope of the curve was still present in the CHLOS group, but the depression (~25%) was less pronounced than that observed in the CHVEH group (~36%, Table). This difference, however, was not significant because of the great variability of the CHVEH group.

Aortic Nerve Sensitivity in the Physiological Range

When the analysis of aortic nerve activity was restricted to a more physiological range of pressure changes (±10 mm Hg from the respective baseline control pressure), a different pattern was observed. In this range, a greater depression was observed in the gain of CHVEH when compared with SHAMVEH (~57%, from 5.05±0.33 to 2.18±0.37%/mm Hg; see Fig 3, left panel). In the losartan-treated group, CH still depressed the gain (~34%, from 4.97±0.33 to 3.30±0.33%/mm Hg), but the depression was significantly smaller than that of CHVEH. As observed in the right panel of Fig 3, aortic nerve activity was corrected during increases but not pressure decreases from the basal value. The gain of SHAMVEH, CHVEH, SHAMLOS, and CHLOS afferents plotted against the respective baseline pressure (inset in Fig 3) showed a significant depression after CH in both CHVEH and CHLOS, but in the absence of Ang II effects, the reduction in the gain was significantly smaller than that observed in the CHVEH group (3.30±0.33 versus 2.18±0.37%/mm Hg, Table). The inset also discriminates between the different effects of chronic

AoNi indicates aortic nerve activity; AP, arterial pressure.

Values are mean±SEM. Pressure values are expressed as systolic/diastolic (mean); n=6 per group. Significance at P<.05; * vs SHAM; † vs VEH; ‡ CHLOS vs SHAMLOS.

### Figure 2

**Normalized aortic nerve activity/systolic pressure curves of normotensive (SHAM, left) and hypertensive (CH, right) rats treated with vehicle (upper panels) or losartan (lower panels).** Curves were obtained on day 4 after coarctation or sham surgery.

**Figure 3.** Percent changes of aortic nerve activity in the physiological range of pressure changes of coarcted (CH) and sham-coarcted rats (SHAM) treated chronically with vehicle or losartan. Relationships were determined on the 4th day after surgery. C represents the control pressure of each group. Inset: Reductions in the slope of the afferent discharge (gain) induced by coarctation in vehicle- and losartan-treated groups. Significance at P<.05; * vs SHAM; † vs VEH; ‡ CHLOS vs SHAMLOS.
Losartan treatment: (1) the pressure-lowering effect demonstrated by the displacement of the points to the left, according to the reduction of baseline blood pressure, and (2) the partial restoration of afferent gain during establishment of hypertension, since the line representing the magnitude of gain reduction was significantly smaller in the presence of losartan. On the other hand, losartan did not change the sensitivity of the afferent discharge in SHAM rats.

Discussion

The present new set of data demonstrates that Ang II, activated by CH, impairs the aortic nerve afferent activity/presence relationship, depressing the gain in the physiological range of pressure fluctuations and increasing the variability of the afferent discharge. The depression of aortic nerve sensitivity after coarctation is significantly smaller in animals receiving chronic AT1 receptor blockade. This effect occurs simultaneously with the pressure-lowering effect of losartan.

In previous studies on baroreceptor reflex control of heart rate during the development of hypertension, we demonstrated activation of the renin-angiotensin system in the chronic phase of CH,26,27 depression of both reflex bradycardia and reflex tachycardia by the increased levels of endogenous Ang II,20,21 and complete normalization of the baroreceptor reflex control of heart rate by chronic treatment with losartan. In this model of hypertension, we also described that the sensitivity of aortic baroreceptors was reduced, with a blunted afferent activity/presence relationship occurring during the chronic phase.27 What we show here is that part of the depression of baroreceptor reflex control of heart rate could be attributed to the effects of Ang II on the afferent signaling of pressure levels by aortic baroreceptors. The presence of Ang II binding sites in the central and peripheral processes of the vagus nerve, in the nodose ganglion, and in the brain stem nuclei containing terminal projections,22,23 together with the demonstration of decreased receptor density in the nucleus tractus solitarii after sinoaortic denervation,24 suggested that Ang II could modulate the transmission of neuronal inputs from the periphery to the central nervous system. Our data, showing that the sensitivity of afferent discharge in losartan-treated CH rats is markedly increased relative to their sham-coarcted controls, confirm the previous suggestion and demonstrate that this effect is mediated by AT1 receptors.

Both AT1 and AT2 receptor subtypes have been mapped in the central nervous system of the rat and of humans,4,6 but most of the functional Ang II effects are mediated by the G protein–coupled AT1 receptor. In addition, brain stem structures involved in cardiovascular control such the nucleus tractus solitarii and dorsal motor nucleus of the vagus, as well as the area postrema, have been shown to contain AT1–Ang II receptors exclusively.4,6 The AT1-mediated Ang II–depressing effect on the baroreflex is very complex, involving, as shown here, changes in baroreceptor afferent activity. Previously, it has been shown that Ang II also has an inhibitory effect on vagal efferents2,13 and attenuates sympathetic activity.9,15 It is possible that both the depression of reflex bradycardia by Ang II administration into the nucleus tractus solitarii of conscious19 or anesthetized rats10,20 and the improvement of the bradycardic response by endogenous block-
baseline firing pattern of Ang II–sensitive neurons in the rat mediad nucleus tractus solitarii, but only to reverse the increased firing and to block the excitation induced by Ang II administration. 31

In summary, the present data showed that Ang II, stimulated after CH and acting on AT1 receptor, depresses the gain of aortic nerve afferents during increases and decreases in pressure, thus contributing to the deficient signaling of pressure levels by aortic baroreceptors in the chronic phase of hypertension. Chronic treatment with losartan, in addition to having a blood pressure–lowering effect, enhances the sensitivity of aortic nerve discharge during loading and unloading of receptors in the physiological range of pressure changes.
