A Comparison Between Systolic and Diastolic Pulse Contour Analysis in the Evaluation of Arterial Stiffness

Ernst-R. Rietzschel, Eva Boeykens, Marc L. De Buyzere, Daniel A. Duprez, Denis L. Clement

Abstract—Several methodologically independent measures of arterial stiffness derived from either the systolic or diastolic segments of the arterial pulse have been proposed. The exact nature of the large and small artery elasticity indices (C1 and C2, respectively) derived from diastolic pulse contour analysis remains largely unexplored, although C2 has controversially been termed to be “oscillatory” and “reflective.” We investigated the relation between C2 and, respectively, a prototype of arterial reflectivity (ie, the augmentation index, AIx) and a covariate of arterial reflectivity (body height). A validated transfer function is used to transform a tonometrically obtained radial pressure wave into an ascending aortic pressure wave, from which AIx is derived using systolic pulse contour analysis. Diastolic pulse contour analysis using a modified Windkessel model is used to derive C1 and C2. One hundred subjects, who were free from atherothrombotic disease and 19 to 77 years of age, with a wide pressure range (97 to 186/52 to 104 mm Hg) were studied. Mean values of C1, C2, AIx, and body height were, respectively, 13.8±4.3 mL/mm Hg×100, 128.5±24.9%, and 169±9 cm. Coefficients of variation were 32.8% for C1, 33.3% for C2, and 6.7% for AIx. C2 was significantly and inversely correlated to AIx ($r=−0.707$, $P<0.001$). Both AIx and C2 were correlated to body height ($r=−0.487$, $P<0.001$, and $r=0.514$, $P<0.001$). In conclusion, the results of this study provide the first clinical evidence that validates a probable biophysical equivalent of the C2 element of a third-order, 4-element modified Windkessel model. We suggest that C2 is, at least in part, a measure of arterial wave reflectance. However, although short-term reproducibility of AIx is excellent, C2 showed markedly increased variability with the devices used. (Hypertension. 2001;37:e15-e22.)

Key Words: arteries - pulsatile flow - wave reflections - Windkessel model - hypertension, diagnosis - reproducibility of results

Hemodynamics research has shifted away from a steady-flow approach toward a pulsatile flow approach, because the former was less predictive in relation to cardiovascular morbidity and mortality.1-5 The growing importance of pulsatile pressure indices (systolic blood pressure [SBP] and pulse pressure) paralleled the notion that not only increases in systemic vascular resistance (SVR) but also increases in arterial stiffness are important in the pathophysiology of hypertension.6,7 This interest in the arterial cushioning function of pulsatile flow has given us a myriad of arterial parameters of global vascular elastic behavior derived from the arterial pressure pulse waveform.11-13 Wave reflection occurs at sites of discontinuity in calibre (bifurcations, branching points, and arterioles) or discontinuity in elastic properties (atherosclerosis) along the arterial tree.14 Changes in amplitude and timing of wave reflections play a key role in aortic hemodynamics and, on a broader level, give us information on how the arterial vasculature affects the heart.15-19 The SphygmoCor BPAS-1/A device (model SPT-301, PWV Medical Pty Ltd) calculates a number of parameters of ventriculo-arterial coupling and wave reflectance, of which the augmentation index (AIx) is preeminent.11,20,21 Another approach in analyzing the arterial pulse is to regard the waveform as a basic pattern of exponential decay on which damped oscillations are superimposed, building on the “Grundform” - “Grundschiungung” concept pioneered by Otto Frank.22 The Windkessel models of the vasculature9,23-25 typify this last approach, and one of these is used by the recently introduced HDI/Pulsewave CR-2000 (Hypertension Diagnostics Inc) to quantify the circulation in terms of SVR, large artery elasticity index (C1), small artery elasticity index (C2), and inductance (L).24-27
Recently, in the field of arterial stiffness, several authors have underscored the need, in addition to uniformity of terminology, for comparisons of techniques to ascertain which methodology (or methodologies) best suits the different research questions facing us.28,29 Indeed, comparative data between different stiffness indices or devices is very scarce, and, more specifically, data assessing the parameters of Windkessel modeling with reflectivity indices are currently lacking.

The goal of this study is to compare 2 methodologically different techniques, predominantly analyzing either the diastolic decay or the systolic segment of the arterial waveform, to describe global vascular elastic behavior. Specifically, C2 as a putative biophysical equivalent of wave reflectance will be assessed. Short-term reproducibility of the 2 techniques used is also analyzed within a single population with a wide pressure and age range.

Methods

Subjects

We enrolled 100 healthy white subjects (41 men, 59 women) with wide age and blood pressure ranges (mean age 46.0 ± 15.1 years and range 19 to 77 years; mean SBP 129 ± 19 mm Hg and range 97 to 186 mm Hg; mean diastolic blood pressure [DBP] 73 ± 11 mm Hg and range 52 to 104 mm Hg). Mean body height was 169 ± 9 cm with a mean weight of 71.6 ± 14.4 kg and a resulting mean body mass index (BMI) of 25.5 ± 4.9 kg/m². Uncomplicated hypertension was present in 32 subjects, and of these, 27 were currently taking antihypertensive medication. None of the subjects had taken any vasoactive drugs in the past 24 hours before the examinations. Any history of cardiac or vascular disease (including cerebrovascular, renovascular, and peripheral vascular disease) was an exclusion criterion. None of the subjects suffered from known endocrine, hepatic, or renal disease. All subjects gave informed consent to be enrolled in the study, which was approved by the local medical ethics committee.

Study Protocol

The experiments were performed between 8:00 and 10:00 AM, after an overnight fast and abstinence from tobacco, alcohol, tea, or coffee. The subjects were allowed 30 minutes of supine rest after the tonometer has been applied. The obtained waveforms are calibrated with a pressure value (cuff placed on the contralateral arm with respect to the tonometer). A computer-based third-order, 4-element modified Windkessel model of the circulation is used to match the diastolic pressure decay of the tonometrically obtained waveforms and to quantify changes in arterial waveform morphology in terms of SVR, C1, C2, and L. The values of C1, C2, and L given in the report are weighted averages of the values obtained on individual waveforms during a 30-second recording period.26,27,30

SVR is calculated as mean arterial pressure (MAP) divided by cardiac output (CO). MAP is derived from the waveform analysis (after calibration with the oscilometrically obtained blood pressure) by integrating the area under each beat and then calculating the average of all beats in the waveform analysis. CO is calculated from a multivariate algorithm, using cardiac ejection time (CET) derived from the radial artery (see Appendix). The multivariate algorithm includes age, HR, body surface area (BSA), and CET and was derived from and tested against measurements of CO using indocyanine green dye dilution measured CO.26,40

The shape of the diastolic decay curve can be represented as the solution to a third-order differential equation with 6 unknown “A” parameters. The “A” values are obtained through a nonlinear curve-fitting routine that matches the shape of the third-order equation to the diastolic decay of the waveform. From the different “A” values and from the previously obtained value of SVR the different elements of the modified Windkessel model (C1, C2, and L) can be calculated.

Short-Term Reproducibility

Dual measurements were performed in random order with each device. Only measurements in which the tonometer was completely removed and subsequently reapplied (on the ipsilateral side) within a time frame of 5 minutes were counted as repeat measurements and withheld for analysis. These criteria were met in all subjects.

Statistical Analysis

Statistical analysis was performed using SPSS for Windows release 9.0. All parameters are given as mean ± SD. Relevant parameters were tested for normality using a Kolmogorov-Smirnov test. Parameters were compared between groups using ANOVA. Relations between stiffness parameters and body height were assessed using partial Spearman ρ correlations. Possible confounders were identified first via univariate correlates (continuous variables) or ANOVA (categorical variables) and subsequently assessed using multivariate regression analysis. Standardized residuals of z scores of linear regression analysis between AIX and C2 were withheld for further analysis. Coefficients of variation were calculated as the SD of the difference between 2 measurements divided by the mean value of the mean of both measurements. Reproducibility data are given as Bland-Altman plots that depict percentual differences between 2 measurements plotted against the mean of 2 measurements.41 The proportion of biological variability in the overall variability was...

estimated using multivariate linear regression. A value of $P<0.05$ was considered statistically significant.

## Results

The Table summarizes the arterial stiffness indices (C1, C2, and AIx), estimates of CET, and stroke volume (SV) obtained by the HDI/Pulsewave CR-2000, as well as coefficients of variation of these parameters. Univariate correlates of C2 comprised ($P<0.01$, except when indicated otherwise) MAP ($r=-0.222$), SBP ($r=-0.587$), age ($r=-0.566$), body height ($r=0.514$), DBP ($r=-0.516$), pulse pressure ($r=-0.442$), body surface area ($r=-0.266$), and BMI ($r=-0.207$, $P<0.05$). Univariate correlates of AIx comprised ($P<0.01$) age ($r=0.659$), MAP ($r=0.555$), body height ($r=-0.487$), SBP ($r=0.483$), DBP ($r=0.469$), pulse pressure ($r=0.320$), BMI ($r=0.304$), and body surface area ($r=0.197$).

In addition to confounders withheld from the univariate analysis (MAP, age, and body height), gender and a history of hypertension/habitual antihypertensive drug use were identified: Women had significantly a lower C2 (5.0±2.6 versus 7.2±3.5 mL/mm Hg·100, $P<0.01$) and significantly higher a AIx (135±24 versus 119±24%, $P<0.01$) than men. Subjects who habitually took antihypertensive drugs had a significantly lower C2 (4.2±2.8 versus 6.3±3.1 mL/mm Hg·100 for drug-free subjects, $P=0.01$) and a nonsignificantly higher AIx (137±18 versus 126±26% for drug-free subjects, $P=0.09$). However, in a multivariate regression analysis neither gender nor habitual antihypertensive drug use added to a model that included MAP, age, and body height. Collinearities could be inferred because women, despite similar age and blood pressure compared with men, were significantly shorter ($P<0.01$) and subjects who habitually took antihypertensive drugs had significantly higher blood pressures ($P<0.01$), were older ($P<0.01$), and were shorter ($P<0.01$) than their drug-free counterparts.

The regression plots between AIx, C2, and body height are shown in Figure 1. The correlations between body height and AIx and C2 remained significant after correction for blood pressure and age ($r=-0.345$, $P<0.01$, and $r=0.314$, $P<0.01$, respectively, for AIx and C2 versus height).

AIx was significantly and inversely correlated with C1 ($r=-0.424$, $P<0.001$) and C2 ($r=-0.707$, $P<0.001$, Figure 2). After controlling for age, height, and blood pressure (MAP), AIx and C2 were still significantly and inversely correlated ($r=-0.312$, $P<0.001$). The correlation between C1 and AIx was lost after correction for age ($r=-0.161$, $P>0.05$).

Coefficients of variation were calculated and averaged 6.7% for AIx, 32.8% for C1, and 33.3% for C2 (Table). Bland-Altman plots were constructed for AIx, C1, and C2 and demonstrate that the 95% confidence interval of the percentual variation varied from −12.4% to +13.8% for AIx, from −63.3% to +69.1% for C1, and from −57.9% to +72.8% for C2. Figure 3 depicts Spearman correlations between first and second measurement of each parameter on the left and corresponding Bland-Altman plots on the right. Differences (absolute and percent) between the dual measurements of C1, C2, and AIx were calculated; no correlations were found between the differences of C1, C2, and AIx and age, height, weight, blood pressure, or heart rate (HR).

Variability in measurement of C1 was not a predictor of variability in measurement of C2 and vice versa.

To identify the reasons for divergence and the apparent relative overestimation of C2 in a subgroup of subjects, further analysis was performed on the standardized residuals'
z scores of the regression between C2 and AIx. Distance from the regression line between C2 and AIx, expressed as z scores, correlated significantly \((P < 0.01)\) with HR \((r = -0.380)\), MAP \((r = -0.310)\), and body height \((r = 0.267)\). Mean z scores of standardized residuals for MAP and HR quartiles are shown in Figure 4 (between group differences analyzed using 1-way ANOVA; \(P < 0.01\) and \(P = 0.014\) for MAP and HR, respectively). A stepwise gradient of the z scores in both HR and MAP quartiles can be clearly seen.

Discussion

This study is the first to compare 2 methodologically different techniques, analyzing either the diastolic decay or the systolic segment of the arterial waveform, to describe global vascular elastic behavior. Our results demonstrate that C2 and AIx are significantly and inversely correlated, which raises the possibility that in addition to AIx, C2 could also be a descriptor of reflective phenomena.

However, before reaching this conclusion, possible confounders of the relation between C2 and AIx should be addressed. In addition to the covariates of C2 and AIx previously identified in literature (age and blood pressure), we investigated the effect of body height, because arterial wave reflections are not only dependent on arterial stiffness but are also related to the length of the arterial path and a fortiori to body height.\(^{11,42–44}\) We found significant correlations between body height and C2 and AIx. The correlation between C2 and body height has not been described previously and is approximately of the same magnitude as the inverse correlation we confirmed between AIx and body height, which has been described previously. In these reports, shorter stature was associated with an increase in magnitude and earlier return of reflected waves due to a shorter arterial tree. In contrast, body height had only marginal effects on nonwave reflection–related stiffness indices. Because of a theoretical relation between body size and HR, on the basis of data from comparative physiology (ie, increasing HR with decreasing body size of the species), as well as on scarce human data, we took care to exclude an effect of HR.\(^{45–47}\) After adjustment, the correlation between C1 and AIx was lost; however, the correlation between AIx and C2 did not change significantly after correction for age, height, and blood pressure.

The concept of wave reflectance is preeminent in a controversy in literature concerning the nature of C2, which has (arbitrarily) been termed to be “oscillatory” and “reflec-
effects on an arteriolar level. In the study of reflectance predominantly as dilators of small arteries with much less sodilators. Nitroglycerin and nitroprusside have their effect on C2 were less than the effects of the nitrovasodilators (nitroprusside and nitroglycerin) largely independent of effects on SVR. On the basis of the results, C2 was claimed to represent “distal (“small arterial”) compliance. The evidence for this stems largely from vasodilatory experiments using nitroprusside, nitro-glycerine, and hydralazine. It was observed that these drugs induced increases of C2 several-fold larger than increases in C1, which were in the case of the nitrovasodilators (nitroprusside and nitroglycerin) largely independent of effects on SVR. On the basis of the results, C2 was taken to represent a measure of “small arterial” and hence “distal” compliance. It should be noted that the effects of hydralazine on C2 were less than the effects of the nitrovasodilators. Nitroglycerin and nitroprusside have their effect predominantly as dilators of small arteries with much less effect on an arteriolar level. In the study of reflectance phenomena, arterial dilators are characterized by a prominent reduction in wave reflectance with minimal effect on SVR. Hydralazine is more representative for arteriolar dilators, which are characterized by prominent reductions of SVR with minimal effect on wave reflections. Hence, with hindsight, these earlier published concepts could equally have been explained by modulation of wave reflectivity. Thus, for a parameter that has been termed reflective, distal, and small artery, the data that support the latter 2 claims may actually be more supportive of a reflective nature of C2.

The position of C2 relative to the regression line with Alx is influenced by blood pressure and HR. Lower blood pressures and/or slower HRs give rise to a gradient that favors relative overestimation of C2. The inverse holds for higher blood pressures or faster HRs (Figure 4). The pressure-dependent gradient can be explained on the basis of the calculation of SVR. Lower MAP values yield lower SVR values, which independently from the waveform analysis (the “A” indices) will increase values of C1, C2, and L (see Appendix). The overestimating gradient produced by decreasing HR cannot be explained by the effect on SVR. A lower HR would (because of a lower CO and thus higher SVR) be expected to cause a relative underestimation of C2. These findings are contrary to the observed data, and we can only surmise a potent, opposite effect of HR on the derivation of the “A” values.

**Short-Term Reproducibility**

A short-term reproducibility analysis was performed and the results indicate a wide gap between the coefficients of variation of C1 and C2 (33% and 34%, respectively) and of Alx (7%). The level of variability for Alx is very similar to values previously reported. Causes of variability could occur at 3 separate stages (signal acquisition, signal calibration and waveform analysis), which will therefore be individually addressed.

**Signal Acquisition**

Both devices use a tonometer for recording the radial arterial pulse wave. The SphygmoCor BPAS-1/A device uses a Millar hand-held tonometer with an external micromanometer tip. There is general agreement that application tonometry can accurately reproduce intra-arterial waveforms (when conditions of correct application are achieved, which seems to be the case in the majority of subjects). The study by Sato et al showed an excellent relation between invasive and tonometric signals with a flat gain up to 7Hz, which covered most of the frequency ranges of interest. However, Alx retains some dependency on the high-frequency content of the signal (8 to 10 Hz). Noise reduction accomplished by introducing a low-pass filter in the system in the range of 9 to 12Hz could therefore be responsible for underestimation of Alx obtained noninvasively compared with invasively obtained Alx. The HDI/Pulsewave CR-2000 device uses a proprietary tonometer (see Methods) in combination with a “holding and positioning device” and an angulated “wrist stabiliser,” which ensures a constant wrist position and a complete stability of position after the tonometer has been applied, in contrast with the
SphygmoCor BPAS-1/A pencil probe, which has to be manually held in position. Consecutive measurements with the tonometer kept in fixed position might be very reproducible but do not comply with daily reality, neither in cross-sectional population studies (or as proposed in risk stratification) nor in longitudinal interventional or observational studies. Therefore, we opted to completely remove the tonometers from the skin between measurements. In these conditions, the only theoretical advantage of the stabilized HDI tonometer is a more constant position within a single measurement. This theoretical advantage was, however, not translated into improved reproducibility in our population.

Because variability in measurement of C1 was not a predictor of variability in measurement of C2 and vice versa, acquisition of the signal or bad-signal quality does not seem to be the prime suspect in the greater variability of the HDI/Pulsewave CR-2000. There is no published information on the HDI proprietary tonometer regarding the accuracy of the tonometrically obtained radial artery waveform compared with intra-arterial recordings.

**Signal Calibration**

In both devices, the peripheral pressure waveforms obtained at the radial artery are calibrated with a blood pressure value determined at the brachial artery. This potentially introduces a systematical error because it assumes equivalence between radial and brachial pressures. Although there is a degree of systolic amplification from brachial artery to radial artery, the differences in pressure are likely to be very small and probably insignificant in comparison to the error introduced by noninvasive blood pressure measurement per se. Furthermore, this systematical error occurs only in the SphygmoCor BPAS-1/A device with regard to the central aortic pressure data; because AIx is an expression of the relative height of 2 parts of the same waveform, this systematical error is not present in the calculation of AIx. In contrast, all “A”-dependent components of the modified Windkessel model (C1, C2, and L) are pressure dependent, because SVR (calculated as MAP/CO) is used in the calculation of all 3. Inaccuracies in measurement of MAP will therefore introduce inaccuracies in SVR and a fortiori in C1, C2, and L.

**Waveform Analysis**

In the SphygmoCor BPAS-1/A, an averaged radial pressure waveform is derived from an 8-second recording, which is used to derive a corresponding ascending aortic pressure waveform using an integral GTF. Because AIx is calculated on the ascending aortic waveform, the accuracy of AIx hinges on the accuracy of these GTFs. Since initial publication, several authors have independently produced similar GTFs and provided validating evidence. GTFs were obtained in individuals in steady state and during hemodynamic transients (after vasodilatation with nitroglycerine and during handgrip maneuvers) and used to synthesize ascending aortic pressure waves, which were compared with invasively recorded pressure waves. Induction of hemodynamic transients, despite producing marked variations in hemodynamic status, had only a marginal effect on the calculated GTFs, which remained practically identical to steady-state GTFs. Karmanoglu et al constructed patient-specific transfer functions, but these proved to be only marginally better than a GTF in matching ascending aortic pressure data. The authors concluded that clinically acceptable predictions of central aortic pressure and waveform could be obtained by mathematical manipulation of radial pressure waves using a single GTF and that this seems to hold true in a wide variety of hemodynamic states. These conclusions are, however, not universally accepted, and the main criticisms are the small number of subjects in the validating studies, the variations in methodology in the cited validating studies, and the inherent problems related to the noninvasive calibration of the radial artery waveform as discussed above.

In the HDI/Pulsewave CR-2000 device, a 30-second collection of radial artery waveform data are analyzed using a third-order, 4-element modified Windkessel model of the circulation, matching the diastolic pressure decay using a proprietary nonlinear curve-fitting routine. The advantages and shortcomings of Windkessel models are well known and described in literature. Three main problems with the methodology should be addressed. First, the model assumes a measurement-site independence, a assumption that has been shown to be unfounded by the study of Fogliardi et al. Second, the model seems to be critically dependent on which segment of the diastolic decay curve is used, and wide variations of “A” values can be produced by small differences in portions of the diastolic decay used for parameter estimation. Third, induction of hemodynamic transients seems to exacerbate the problems created by the assumption of measurement-site independence.

Causes for the increased variability of the HDI/Pulsewave CR-2000 device could theoretically be found at several stages. However, taking into account that variability in C1 was not a predictor of variability in C2 and vice versa and that the device has reproducible measurements of SV (and CO) reflecting good reproducibility of CET, which is also derived from the same radial waveform with minimal variability, it must be assumed that signal acquisition or bad signal quality does not seem to be the prime suspect in the greater variability of the HDI/Pulsewave CR-2000 device. Furthermore, only a minimum of variability can be attributed to biological variations in blood pressure or HR between measurements in supine subjects at rest during a 5-minute time frame (the measurements were, as expected for subjects in supine rest, small: in the order of 3% to 4% blood pressure or HR variability, accounting for at most 8% to 9% of the variability of C1 or C2 in a stepwise multiple regression analysis). It therefore seems likely that the proprietary parameter estimating algorithm of the HDI/Pulsewave CR-2000 is primarily responsible for the variability of C1 and C2. Although reproducibility does not imply validity, in future clinical or validating studies with stiffness devices, power calculations on the number of subjects needed for inclusion are likely to be several times larger for the HDI/Pulsewave CR-2000 device.

In conclusion, the results of this study provide the first clinical validating evidence for a probable biophysical equivalent of the C2 element of a third-order, 4-element modified Windkessel model. We suggest that C2 is, at least in part, a measure of arterial wave reflectance. However, although...
short-term reproducibility of Alx with the SphygmoCor BPAS-1/A is good, measurement of C1 and C2 with the HDI/Pulsewave CR-2000 showed markedly increased variability.
