Cerebrovascular Regulation

Cerebrovascular Regulation During Transient Hypotension and Hypertension in Humans

Yu-Chieh Tzeng, Chris K. Willie, Greg Atkinson, Samuel J.E. Lucas, Aaron Wong, Philip N. Ainslie

Abstract—The cerebrovasculature dilates or constricts in response to acute blood pressure changes to stabilize cerebral blood flow across a range of blood pressures. It is unclear, however, whether such dynamic cerebral autoregulation (dCA) is equally effective in responding to falling versus rising blood pressure. In this study we applied a pharmacological approach to evaluate dCA gain to transient hypotension and hypertension and compared this method with 2 established indices of dCA that do not explicitly differentiate between dCA efficacy and falling versus rising blood pressure. Middle cerebral arterial velocity and blood pressure recordings were made in 26 healthy volunteers randomized to 2 protocols. In 10 subjects, dCA gain to transient hypotension induced with intravenous nitroprusside was compared with dCA gain to transient hypertension induced with intravenous phenylephrine. In 16 subjects, dCA gain to transient hypotension induced with intravenous nitroprusside was compared with the rate of regulation and autoregulatory index derived from transient hypotension induced with the thigh cuff deflation technique. dCA gain to transient hypotension induced with intravenous nitroprusside was unrelated to dCA gain to transient hypotension induced with intravenous phenylephrine \( (r=0.06; P=0.87) \) and was consistently greater than dCA gain to transient hypotension induced with intravenous phenylephrine \( (0.57 \pm 0.16 \text{ versus } 0.31 \pm 0.20 \text{ cm/s per millimeter of mercury}; \ P<0.01) \). However, dCA gain to transient hypotension induced with intravenous nitroprusside was inversely related to the rate of regulation \( (r=-0.52; P=0.037) \) and autoregulatory index \( (r=-0.66; P=0.005) \). These data indicate that, under our laboratory conditions, dCA appears to be inherently nonlinear with disparate efficacy against rising and falling blood pressure, and dCA gain derived from pharmacologically induced transient hypotension correlates with established nonpharmacological indices of dCA. \( \text{(Hypertension. 2010;56:268-273.)} \)

Key Words: brain circulation ▪ blood flow regulation ▪ blood pressure ▪ hemodynamics ▪ transcranial Doppler

Cerebral blood flow (CBF) is tightly controlled via the static and dynamic properties of cerebral autoregulation (CA).\(^1\) Static CA refers to CBF regulation over gradual and progressive changes in blood pressure, whereas dynamic CA (dCA) refers to CBF control in response to blood pressure changes that occur within seconds.\(^2\) Numerous methods have been used for dCA assessment because of growing recognition that CA impairment is an adverse prognostic indicator for cerebrovascular disease.\(^3\) These methods include rapid thigh-cuff deflation,\(^4\) rapid standing,\(^5\) and transfer function analysis of spontaneously occurring blood pressure and CBF velocity oscillations.\(^6\)

Underlying the quantification of dCA is the principle that blood pressure perturbations incite changes in cerebrovascular tone that act to stabilize CBF. Although it is assumed that this reflex vasomotion is equally effective in attenuating both cerebral hypoperfusion and hyperperfusion,\(^7\) dCA may be more adept at compensating for transient hypertension than for hypotension, as induced by cyclic inflation and deflation of thigh cuffs.\(^8\) However, extrapolation of these data to healthy individuals needs to be done with caution, because asymmetry was only apparent in head-trauma patients under conditions of artificial ventilation and hypocapnia. Furthermore, thigh cuffs only elicited minor changes in blood pressure \( (\approx 8 \text{ mm Hg}) \).\(^8\) Therefore, the possibility that dCA exhibits disparate efficacy in responding to rising versus falling cerebral perfusion pressure requires further consideration.

The “Oxford method” perturbs blood pressure via intravenous injections of vasodilator and/or vasoconstrictor drugs. Although widely used for assessing baroreflex sensitivity, this method has not been applied for dCA evaluation despite potential advantages, in particular the means to separately assess dCA responses to transient reductions and elevations in blood pressure. The objectives of the current study were 2-fold. First, based on the findings from animal studies indicating that cerebral sympathetic nerve activity increases

268
during hypertension, but not hypotension,9 we examined the hypothesis that dCA responds to rising blood pressure more effectively than to falling blood pressure in healthy humans. The second objective was to compare dCA, as determined using the Oxford method against the established rate of regulation (RoR)4 and autoregulatory index (ARI)10 indices derived from the thigh-cuff technique.

Methods

Subjects
Twenty-six healthy fasted subjects (21 men) were recruited to 2 study protocols (A, n = 16; 5 women; B, n = 10 men), which were approved by the Central Regional Ethics Committee and conformed to the standards set by the Declaration of Helsinki. The subjects’ mean age was 26 years (range: 20 to 33 years).

Measurements
The ECG, respiratory flow (Hans Rudolph Heated Pneumotach HR 800), noninvasive blood pressure (Finometer, TNO-TPD Biomedical Instrumentation), right middle cerebral artery flow velocity (MCAv; 2-MHz pulsed Doppler ultrasound, DWL Doppler), and end-tidal pCO2 (ETCO2) sampled from a leak-free mask (gas analyzer model CD-3A, AEI Technologies), were acquired at 1000 Hz via an analog-to-digital converter (Powerlab/16SP ML795, ADInstruments). The Doppler probe was secured with a headband device (Spencer Technologies) to maintain optimal insolation position. From the blood pressure and MCAv waveforms, we determined beat-to-beat mean arterial pressure (MAP) and MCAv values using custom written software in LabView 8.2 (National Instruments).

Protocol
All of the trained subjects were studied in the supine position. After an initial 10-minute stabilization period, baseline data were recorded for 5 minutes. Thereafter, subjects were randomized to 1 of 2 protocols, as described below.

Protocol A: Hypotension Versus Hypertension Comparison
Transient hypotension and hypertension were induced with intravenous bolus injections of sodium nitroprusside (150 to 300 μg) and phenylephrine hydrochloride (200 to 400 μg) in randomized order. For comparison against a more physiological (nonpharmacological) transient hypotensive stimulus, subjects also performed a sit-to-stand maneuver. This involved asking subjects to rapidly assume a standing posture 15 minutes after the completion of the final drug intervention.

Protocol B: Pharmacological Versus Thigh-Cuff Comparison
Transient hypotension was induced with bolus injections of sodium nitroprusside (150 to 300 μg) and the rapid thigh-cuff technique1 in randomized order. All of the subjects were trained to breathe in time with respiratory-related fluctuations. G values were reported without phase delays, because correlation coefficients were greatest when MAP and MCAvmean relations were examined in phase. This is consistent with negligible delays imposed by wave propagation properties of the circulation. Under this construct, perfectly efficient dCA would have G = 0, indicating a constant CBF across a wide range of MAPs, whereas the complete absence of dCA would give G = 1, consistent with a pressure-passive relationship.

Nonpharmacological assessment of dCA was also achieved using 2 complimentary measures derived from the classic thigh-cuff test: the RoR4,11 and the ARI.10 The cerebrovascular conductance index (CVCi) was calculated by dividing MCAvmean by MAP. The MAP, MCAvmean, and CVCi values were determined relative to control values. Control data were taken as the mean of the 4 seconds immediately before thigh-cuff release. The RoR index was defined as:

$$ RoR = \frac{\Delta CVCi/\Delta t}{\Delta MAP} $$

where ΔCVCi/Δt is the slope of the linear regression between CVCi and time, and ΔMAP is the difference between baseline MAP and the average MAP during the 1.0- to 3.5-s period after cuff release.4,11 Consistent with previous studies,11 the RoR was calculated using CVCi (flow/power) rather than the cerebrovascular resistance index (pressure/flow),4 because CVCi may better reflect regional vascular tone under situations where changes in tone lead to changes in flow.12 The dCA response to transient hypotension was also assessed using the ARI from Tieck et al,10 defined as graded coefficients from 0 (absence of dCA) to 9 (strongest dCA). This involved applying a second-order linear differential equation, defined as follows:

$$ dP_n = \frac{MAP - MAP_{base}}{MAP_{base} - CCP} x_2 = x_2_{n-1} - \frac{(x_1 - 2D + x_2_{n-1})}{f \cdot T} $$

$$ x_1 = x_1_{n-1} + \frac{(dP_n - x_2_{n-1})}{f \cdot T} $$

$$ mV_n = MCAv_{mean} \cdot (1 + g \cdot dP_n - k \cdot x_2) $$

where $dP_n$ is the normalized change in MAP relative to the control value (MAPbase) adjusted for the estimated critical closing pressure (CCP) of 12 mm Hg,10 $x_2$ and $x_1$ are state variables (equal to 0 at baseline), $MCAv_{mean}$ is modeled mean velocity, MCAvbase is baseline MCAvmean, $f$ is the sampling frequency (10 Hz), and $n$ is the sample number. The $mV_n$ generated from 10 predefined combinations of parameters T (time constant), D (dampening factor), and k (autoregulatory gain) that best fit (quadratic error: 30-second window) the actual MCAvmean recording was taken as an index of dCA.

Statistical Analysis
Data were assessed for normality and log transformed if there was evidence of nonnormality. All of the variables were reported as mean±SD. For the appraisal of the agreement between $G_{down}$ and the RoR and ARI indices, Pearson’s product-moment correlation coefficients and least-squares regression analysis were used. Correlations between variables were compared using Steiger’s method.13 Because ARI is measured on a 0 to 9 discrete scale and is, therefore, borderline parametric in nature, this variable was also analyzed with an ordinal regression model.14 Specific a priori defined comparison of changes in ETCO2 during hypotension and hypertension against baseline were conducted as planned using Student’s paired t test. Differences in dependent variables were assessed using 1-way repeated-measures ANOVA (Huynh-Feldt corrected). Post-hoc analyses were made with Student’s paired t test. Statistical significance was set at P<0.05, and the Bonferroni correction was applied where appropriate to control for type 1 error associated with multiple testing. Analyses were conducted using SPSS 16.0.2 (SPSS Inc) and Statview 5 (SAS Institute).
Hypotension Versus Hypertension Comparison

The Table summarizes the hemodynamic changes in MAP and MCAvmean after the nitroprusside and phenylephrine injections and after standing from a seated position. In all of the subjects, nitroprusside and standing induced a fall in MAP, and phenylephrine induced a rise in MAP (Figure 1). The time interval between the point at which MAP begins to change to the first local maximum change was 19 ± 4 s for nitroprusside injection (P = 0.10 versus phenylephrine), 11 ± 1.2 s for standing (P < 0.01 versus phenylephrine), and 23 ± 6.9 s for phenylephrine injection. The magnitude of absolute MAP change was greater with standing but was similar between nitroprusside hypotension and phenylephrine hypertension. In contrast, the MCAvmean rise with phenylephrine was significantly smaller than the MCAvmean reduction with both nitroprusside injection and standing. Compared with baseline (39 ± 3.7 mm Hg), average ETCO2 did not differ during nitroprusside hypotension (40 ± 4.1 mm Hg; P = 0.080 versus baseline), stand hypotension (38 ± 4.0 mm Hg; P = 0.064 versus baseline), or phenylephrine hypertension (39 ± 2.8 mm Hg; P = 0.88 versus baseline).

Figure 2 shows the differences among G\textsubscript{down}, G\textsubscript{up}, and G\textsubscript{stand} for all of the subjects recruited to protocol B. With the exception of 2 individuals, both G\textsubscript{down} and G\textsubscript{stand} were consistently greater than G\textsubscript{up}. Across all of the subjects, the average G\textsubscript{down} (0.57 ± 0.16 cm/s per mm Hg; \(r = 0.93 \pm 0.089\)) was similar to G\textsubscript{stand} (0.58 ± 0.15 cm/s per mm Hg; \(r = 0.95 \pm 0.028\)), and both were substantially greater than G\textsubscript{up} (0.31 ± 0.20 cm/s per mm Hg; \(r = 0.72 \pm 0.22\)). Results

Figure 1. Data from one subject with very prominent asymmetric hemodynamic responses to intravenous nitroprusside, phenylephrine, and standing from the seated position relative to baseline. Baseline is defined as the 10 s before a change in MAP. Nitroprusside (B)-induced hypotension and sit-to-stand (C) hypotension were accompanied by concurrent reductions in MCAvmean. In contrast, phenylephrine (A)-induced hypertension was associated with negligible changes in MCAvmean in this individual. The onset of hypotension and hypertension was associated with approximately linear increases and decreases in the CVCi index. G\textsubscript{down} (E; 0.61 cm/s per mm Hg) and G\textsubscript{stand} (F; 0.70 cm/s per mm Hg) were clearly different from G\textsubscript{up} (D; 0.11 cm/s per mm Hg). Horizontal bars denotes segments of data take for gain calculations.
Pharmacological Versus Thigh-Cuff Comparison

In contrast to nitroprusside injections, the thigh-cuff technique caused a sudden drop in MAP (20 ± 4.5 mm Hg) that returned to baseline over a variable time period (mean: 38 ± 6 s). Across all of the subjects, $G_{\text{down}}$ was inversely related to both RoR ($r = -0.52$; $P = 0.037$) and ARI ($r = -0.66$; $P = 0.005$). There was no significant difference between these 2 correlation coefficients ($P = 0.25$), and the standardized estimates of the 2 regression slopes were similar ($-0.5$ to $-0.6$). The relationship between $G_{\text{down}}$ and ARI was also statistically significant ($P = 0.006$) when the ARI data were analyzed with an ordinal regression model. The equations relating $G_{\text{down}}$ to RoR and ARI were as follows:

$$\text{RoR} = 0.49 - 0.23 \times G_{\text{down}} \quad \text{(Standard error of estimate 1.1)}$$

$$\text{ARI} = 8.03 - 4.46 \times G_{\text{down}} \quad \text{(Standard error of estimate 0.08)}$$

**Discussion**

**Main Findings**

The 3 major new findings of this study are as follows: (1) across subjects, $G_{\text{down}}$ and $G_{\text{stand}}$ were consistently greater than $G_{\text{up}}$; (2) both $G_{\text{down}}$ and $G_{\text{stand}}$ were unrelated to $G_{\text{up}}$; and (3) dCA, as indexed by the RoR and ARI, showed an inverse relationship with $G_{\text{down}}$. These findings indicate that dCA may be better adapted to compensating for rising than for falling blood pressure in humans. They also show that dCA responses to pharmacologically induced hypertension are correlated with established indices (RoR and ARI) of dCA.

**CBF Responses to Pharmacologically Induced Hypotension and Hypertension**

Aaslid et al. reported that dCA was more adept at compensating for transient hypertension than hypotension induced by cyclic inflation and deflation of thigh cuffs in head injury patients. Consequently, they hypothesized that this “asymmetry” may be a fundamental feature of CA. However, given there was no overt CA asymmetry in the control subjects, and the head injury cohort was artificially ventilated at hypocapnic levels (ETCO$_2$ 32 to 35 mm Hg), this extrapolation may have been misleading. For example, because hypocapnia causes cerebral arteriolar vasoconstriction and improves dCA, this alone may have explained why dCA was more effective in compensating for hypertension in the head-injury cohort. However, our findings that $G_{\text{down}}$ and $G_{\text{stand}}$ were both greater than $G_{\text{up}}$ for the majority of subjects, that both $G_{\text{down}}$ and $G_{\text{stand}}$ were unrelated to $G_{\text{up}}$, and that $\Delta \text{MCA}_{\text{mean}}$ with rising blood pressure was less than $\Delta \text{MCA}_{\text{mean}}$ with falling blood pressure despite similar $\Delta \text{MAP}$ changes following phenylephrine and nitroprusside injections supports the hypothesis that the mechanisms underlying dCA are more effective in responding to acute transient hypertension than to hypotension.

The application of transfer function analysis has shown that dCA exhibits high pass filter characteristics consistent with more effective cerebrovascular control against blood pressure changes that occur slowly in the low (0.07 to 0.30 Hz) and very low (<0.07 Hz) frequency ranges. Because the MAP changes induced with nitroprusside and phenylephrine both occur over $\approx 20$-s intervals, they are well within the range (<0.07-Hz or $> 14$-s cycles) in which CA is thought to be most effective. Therefore, the differences between $G_{\text{up}}$ and $G_{\text{down}}$ are unlikely to be attributable to the frequency-dependent efficacy of dCA. This finding provides the first clear evidence that asymmetrical dCA responses may indeed represent a fundamental property of CA in otherwise healthy humans.

**Assessment of dCA**

The slopes of the linear regression between MAP and MCA$_{\text{mean}}$ ($G$) after nitroprusside and phenylephrine injections were taken as indices of dCA gain to falling and rising blood pressure challenges. This approach is simplistic, as it assumes a linear systems response to blood pressure perturbation. However, the pharmacological method has clear advantage as a means of delineating dCA responses to rising and falling blood pressure across a wide pressure range, an important consideration given that dCA asymmetry cannot be reliably studied using conventional techniques, such as thigh-cuff deflation, which elicits only hypotension, or transfer function analysis of blood pressure and MCA$_{\text{mean}}$ oscillations that are generally of comparatively lower magnitude. Moreover, although thigh-cuffs can elicit muscular pain, nitroprusside and phenylephrine injections often go unnoticed, thus minimizing the confounding effects of emotion on CA responses.

The current study shows that the established RoR and ARI indices calculated from transient hypotension induced by deflating thigh cuffs were equally correlated to $G_{\text{down}}$ derived from nitroprusside injections, suggesting that these indices likely reflect common components of dCA during transient hypotension. However, both RoR and ARI were only moderately related to the $G_{\text{down}}$ index, indicating that the indices

**Figure 2.** CA gain ($G$) for nitroprusside hypotension (down), sit-to-stand hypotension (stand) vs phenylephrine hypertension (up). Line represents the paired responses for an individual (C). With the exception of 2 subjects, $G_{\text{down}}$ and $G_{\text{stand}}$ were greater than $G_{\text{up}}$. Group averages are also shown (M). Repeated-measures ANOVA; $P < 0.01$. *Statistically different from $G_{\text{up}}$.**
should not be used interchangeably. We speculate that differences may relate to the contrasting nature of the 2 stimuli; rapid thigh-cuff deflation causes blood pressure to drop within 1 to 2 heartbeats, exposing the cerebral circulation to an abrupt stimulus, whereas nitroprusside causes blood pressure to fall over a significantly longer timeframe. Nevertheless, the identification of disparate dCA efficacy to rising versus falling blood pressure highlights the inherent limitations of evaluating dCA using linear methods, including thigh-cuff deflation and transfer function analysis. Although our data do not invalidate linear methodologies as ongoing research tools, they underscore the need to further develop techniques that do account for the nonlinear properties of CA.

Finally, it is important to recognize that dCA is not a static property of the cerebrovasculature but rather is a mechanism that operates in conjunction with other homeostatic mechanisms, such as the arterial baroreflex, and may be modulated by factors such as age and baseline resting blood pressure. Indeed, one study reported reductions in transfer function gain between blood pressure and MCAvmean with incremental elevations in blood pressure using a phenylephrine infusion. Although this finding suggests that dCA efficacy alters with changes in steady-state cerebrovascular resistance, it remains unknown how changes in cerebrovascular resistance might differentially alter the dCA response to falling versus rising blood pressure. In the present study, blood pressure was perturbed in both “directions” after a period of steady-state baseline recording. Therefore, although our conclusions are valid for those circumstances where blood pressure transients occur from resting blood pressure levels, the presence and nature of dCA asymmetry in other physiological (eg, exercise) and pathological states (eg, chronic hypotension) associated with higher or lower baseline blood pressure warrant further study.

Potential Mechanisms
Animal data indicate that perivascular cerebral sympathetic nerves are activated during acute hypertension but not hypotension. This raises the possibility that selective cerebral vasoconstriction (secondary to perivascular cerebral sympathetic nerve activation) may partly explain dCA asymmetry. Consistent with this hypothesis, transfer function gain and coherence between MCAvmean and MAP oscillations induced with oscillatory lower body negative pressure increases after α-adrenergic blockade. Although potentially confounded by unexplained hypocapnia, the rise in coherence, which may be interpreted as an increase in linearity between MAP and MCAvmean relations, might be attributable to the loss of dCA asymmetry. Given that human pial arteries are sparsely innervated and are insensitive to topical noradrenaline, it is also possible that dCA asymmetry may relate to differences in intrinsic myogenic responses to hypotension versus hypertension. Finally, animal studies have identified collagen fibers and smooth muscle cells at the entrance of the bridging veins to the cerebral venous sinuses. These histological structures might be part of a venous cuff mechanism that is actively involved in cerebral venous outflow and, therefore, intracranial blood volume regulation. Although the relative importance of this putative mechanism in humans is unclear, we cannot exclude the possibility that venous outflow control contributes to the dCA asymmetry that we have observed.

Perspectives
Effective counterregulation against transient hypertension may reflect an evolutionary adaptation protecting the brain from transient blood pressure surges, such as those normally encountered during rapid eye movement sleep and exercise or those associated with labile hypertension, autonomic dysreflexia, and baroreflex failure. It is, therefore, conceivable that the loss of dCA asymmetry may increase hemorrhagic stroke risk. In addition, there is strong evidence that pharmacological testing of arterial baroreflex sensitivity is a powerful risk stratification tool for cardiac death. With emerging evidence suggesting that baroreflex dysfunction also independently modulates outcomes from acute hemorrhagic stroke, methods that can unobtrusively gauge both baroreflex sensitivity and dCA gain would be desirable. Because the $G_{down}$ metric is correlated with both RoR and ARI scores, the potential use of the pharmacological approach as a combined measure of baroreflex and dCA function should be studied further.

Methodological Considerations
Two methodological considerations warrant discussion. First, changes in MCAv reflect changes in CBF only if the MCA diameter is constant. Previous studies have shown that intra-arterial phenylephrine ($\alpha_1$-adrenoceptor agonist) does not cause any relevant MCA vasoconstriction. Likewise, nitroprusside administered during craniotomy in humans did not cause any relevant MCA vasoconstriction. Likewise, nitroprusside administered during craniotomy in humans did not affect MCA vessel diameter. Therefore, it seems reasonable to assume that changes in MCAv measured via transcranial Doppler ultrasound were proportional to changes in CBF. Second, the drugs used to manipulate blood pressure may have exerted unquantifiable effects on dCA responses by directly altering cerebrovascular resistance downstream from the MCA. However, direct confounding related to nitroprusside seems unlikely given that mechanoregulation of CBF occurs independent of NO-mediated pathways. Likewise, direct confounding because of phenylephrine is unlikely, because the intact blood-brain barrier normally prevents intravascular catecholamines (as opposed to catecholamines released from perivascular sympathetic nerves) from binding to $\alpha_1$-adrenoceptors of cerebral arterioles. Although there is evidence that raised intravascular pressure may compromise the integrity of the blood-brain barrier resulting in “leak through” of intravascular catecholamines, the evidence for this is based on animals studies conducted under conditions that are vastly different from those of the current study, that is, prolonged (hours) periods of extreme hypertension (eg, MAP >180 mm Hg). We acknowledge that new developments in functional MRI will likely provide invaluable insight into how asymmetrical dCA may influence CBF to discrete regions of the brain.

Conclusions
The current study documents an asymmetrical dCA response that is relatively more effective at guarding the brain from transient hypertension than hypotension. Our results also
shows that dCA, as indexed by \( G_{\text{down}} \), is positively related to
the RoR and ARI index derived from the classical thigh-cuff
deflation technique.
