Arterial wall thickening is an early sign of atherosclerosis and is associated with the prevalence and incidence of cardiovascular disease. There are reports of age-related increases of arterial wall thickness (AWT) in several cross-sectional community-based studies; however, rates of change in AWT among middle-aged and older adults have not been defined. Moreover, the relationship between AWT and aortic stiffness after accounting for cardiovascular risk factors has not been defined.

In a subset of individuals from the Multi-Ethnic Study of Atherosclerosis (MESA), we measured AWT and aortic distensibility using cardiac magnetic resonance (CMR) imaging as well as demographic and clinical variables. The purpose of this study was 2-fold. First, we sought to characterize the age, demographic, and sex-specific distributions along with the yearly rates of change of AWT in adults aged >45 years without symptomatic arteriosclerotic disease. Second, we desired to evaluate associations between AWT and arterial stiffness (measured by aortic distensibility and pulse wave velocity [PWV]) in these same individuals.

Methods

Study Population

The first CMR examination from the MESA was initiated by the National Heart, Lung, and Blood Institute (Bethesda, MD) in 2000. This examination was performed to obtain a baseline from which future longitudinal studies could be performed to further understanding of the pathogenesis of atherosclerosis and other cardiovascular diseases in individuals whom were otherwise without evidence of symptomatic arteriosclerotic disease. In the longitudinal follow-up of the fifth examination (MESA5), each subject in the MESA study underwent CMR from April 2010 to February 2012. Institutional review boards at each center approved the study protocol. Of these, only one clinical site (Wake Forest University, Winston Salem, NC) had AWT images acquired in both the baseline and the follow-up CMR studies. Researchers analyzed 371 participants at baseline and 423 participants in the follow-up sessions. We excluded participants with symptomatic arteriosclerotic disease.

Abstract—The study was performed to determine age, sex, and time-dependent changes in aortic wall thickness (AWT) and to evaluate cross-sectional associations between AWT and arterial stiffness in older adults. Three hundred seventy-one longitudinal and 426 cross-sectional measurements of AWT from cardiovascular magnetic resonance imaging studies conducted within the Multi-Ethnic Study of Atherosclerosis were analyzed at 2 points in time, in 2000 to 2002 and then again from follow-up examinations in 2010 to 2012. Aortic wall thickness was determined from a double inversion recovery black-blood fast spin-echo sequence, and aortic stiffness was measured from a phase-contrast cine gradient echo sequence. The thickness of the midthoracic descending aortic wall was measured and correlated to distensibility of the ascending aorta and aortic pulse wave velocity. The average rate of AWT change was 0.032 mm/y. The increase in AWT was greater for those aged 45 to 54 years relative to individuals older than 55 years (P trend<0.001). Ascending aortic distensibility was lower (P<0.001) and pulse wave velocity was higher (P=0.012) for hypertensive subjects. After adjustment for traditional risk factors, distensibility of the ascending aorta was significantly related to AWT in participants without hypertension. Hypertension was associated with increased aortic stiffness independent of aortic wall thickness. (Hypertension. 2015;65:1015-1019. DOI: 10.1161/HYPERTENSIONAHA.114.05080.)

with myocardial scarring (based on the CMR late gadolinium enhancement studies) from the analysis.

**Magnetic Resonance Aortic Wall Thickness and Stiffness Imaging**

Baseline CMR was performed using 1.5-T whole-body magnetic resonance imaging systems (Signa CV/i or Signa LX; GE Medical Systems, Waukesha, WI). A double-inversion recovery black-blood fast spin-echo sequence with ECG gating was used to obtain the AWT images. We acquired axial images of the descending thoracic aorta at the level of the right pulmonary artery. Imaging parameters were repetition time=2 R–R intervals; echo time=42 ms; field of view=36×36 cm; slice thickness=6 mm; echo-train length=32; and matrix size=512×256. In the follow-up examinations, CMR was performed using a 1.5T Siemens scanner (Avanto, Siemens Medical Systems, Erlangen, Germany). The imaging sequence and plane were similar to those used in the baseline, but used a different protocol: repetition times=2 R–R intervals; echo time=66 ms; field of view=36×36 cm; slice thickness=10 mm; echo-train length=17; and matrix size=256×256. Aortic wall thickness was measured by a single observer using the same method and software as described in the MESA AWT study. The thickness of the midthoracic descending aortic wall was measured using electronic calipers at 4 standard positions: 12, 3, 6, and 9 o’clock (QMASS 7.2, Medis, Leiden, The Netherlands). We calculated AWT as the average value of these 4 measurements. Phase contrast cine echo sequence was also obtained to evaluate aortic stiffness in the follow-up study. An aortic sagittal oblique plane with a black-blood sequence was acquired to position the aortic phase-contrast imaging, and also allowed for the measurement of the path length between the ascending and descending aorta. Imaging parameters were as follows: temporal resolution=35 ms; field of view=36×27 cm; slice thickness=10 mm; matrix size=128×96; 1 signal average; and velocity encoding gradient=100 cm/s.

Using validated automated software (ARTFUN, INSERM U678), the study recorded distensibility of the ascending aorta (AAD) and PWV. The study calculated distensibility as AAD (mm Hg⁻¹):=(maximum area ascending aorta−minimum area ascending aorta)/[PP×minimum area ascending aorta]×1000, where PP is the pulse wave pressure measured from the systolic and diastolic pressure during CMR aortic acquisition. Pulse wave velocity was measured as PWV (m/s)/distance (mm)/transit time between ascending to descending aorta (ms). As previously described, the transit time was calculated as the average time difference using the least squares estimate between all data points on the systolic upslopes of the ascending and descending aortic flow curves after peak flow normalization.

**Statistical Analysis**

We performed statistical analysis using SPSS (Chicago, IL). All continuous data were expressed as mean±1 SD. Only those participants with aortic wall imaging at both time points were included in the longitudinal data analysis. For categorical variables, we used a χ² test. An unpaired student t test was used to compare the continuous variables between groups. To detect determinants of AWT changes >10 years, multivariate linear regression analysis was performed that adjusted for the baseline age, sex, body mass index (BMI), race/ethnicity, smoking status, pack-year, low-density lipoprotein, high-density lipoprotein, systolic and diastolic blood pressure, diabetes mellitus, and hypertension status.

For the cross-sectional analysis in the follow-up examination, we first determined the relationship between AWT and the risk factors using the same model described above. To examine the association between AAD and PWV with AWT, we stratified populations by hypertensive status. Ascending aorta distensibility and PWV were continuous variables to determine their associations to AWT. Linear regressions with multivariable adjustments for demographic characteristics and risk factors were performed. Model 1 reflected adjustments for age, sex, BMI, and race/ethnicity, and model 2 demonstrated adjustments for variables in model 1 as well as systolic and diastolic blood pressure, diabetes mellitus, low-density lipoprotein, high-density lipoprotein, current smoking status, and smoking pack years. A 2-tailed P value of <0.05 was considered statistically significant.

**Results**

Table 1 lists demographics and aortic measurements in the latter (MESA5, 2010–2012) exams, and changes of AWT >10 years. The study cohort consisted of 61% non-Hispanic white and 39% black subjects. Aortic wall thickness was significantly different between men and women. Men had thicker aortic walls than women (for men the baseline measure was 2.40±0.44 mm, and during the MESA5 examination it was 2.75±0.26 mm for men, and baseline, 2.32±0.43 mm and MESA5, 2.61±0.26 mm for women), but aortic stiffness measures (ie, AAD and PWV) were similar. The change of AWT >10 years was 0.35±0.48 mm for men and 0.30±0.44 mm for women (P=0.26). The average AWT change was 0.32±0.46 mm in 10 years. The Figure displays the average AWT at the baseline and AWT increase >10 years by age categories (at the

![Table 1. Mean Characteristics of the MESA5 Participants](image-url)
Aortic wall thickness increased more for those with a baseline age of 45 to 54 years and reached a plateau as age increased ($P_{\text{trend}}<0.001$).

In the fully adjusted models, the baseline age, race, and BMI were the major predictors for the rate of change in AWT. Age was inversely correlated with greater rate of change in AWT ($B=-0.013 \text{ mm/y}, P<0.001$, consistent with Figure), whereas higher BMI was related to increased AWT ($B=0.018 \text{ mm/kg/m}^2, P=0.001$). White race was also positively associated with greater AWT increase when compared with black race ($P=0.03$). Blood pressures at baseline were not related to the AWT change.

Among the risk factors examined, AWT in MESA5 was mainly related to older age ($B=0.007 \text{ mm/y}, P<0.001$), higher BMI ($B=0.009 \text{ mm/kg/m}^2, P=0.001$), higher diastolic blood pressure ($B=0.005 \text{ mmHg}, P=0.005$), and lower high-density lipoprotein cholesterol ($B=-0.002 \text{ mm/mg/dL}, P=0.02$).

To study the correlations between aortic morphology and function, Table 2 lists basic demographics, AWT, AAD, and PWV stratified by hypertension status in the latter examination (2010–2012). When comparing these 2 groups, we found that AWT was not different ($P=0.35$) but distensibility was lower ($P<0.001$) and PWV was higher ($P=0.012$) in those with hypertension. Multivariable linear regression analyses (Table 3) demonstrated that distensibility was significantly correlated to AWT in the cohort without hypertension. Aortic wall thickness predicted PWV in the first model (model 1; Table 3) in those with hypertension, but this correlation diminished after adjusting for more variables (model 2; Table 3).

### Discussion

Using CMR, we analyzed the change of aortic stiffening (distensibility and pulse wave velocity), thoracic AWT, and the relationship of these changes to traditional cardiovascular risk factors in an older (aged 55–85 years) population that was free of established cardiovascular disease. Change in AWT using the same magnetic resonance imaging methods has been previously evaluated in a cross-sectional study of 198 younger individuals. Compared with the 0.07 mm AWT increase in 5 years reported by the previous study in younger participants, our findings reveal a greater increment of change in older individuals free of symptomatic atherosclerotic disease: 0.16 mm in 5 years longitudinally.

After multivariable adjustment, the primary factors related to change in AWT were age, race, and BMI. Although older age was associated with increased AWT, the rate of increase peaked in those 45 to 55 years in age and then plateaued with advancing age. This is an interesting finding, but we cannot rule out survival bias. BMI remained a significant factor associated with an increased AWT. Our results concerning differences in sex were consistent with previous studies, men had greater AWT than women, but AWT increase >10 years was similar between sexes.

In the longitudinal studies reported by Lam et al from the Framingham Heart Study, morphological changes measured by the aortic root diameters were greater in men and women with obesity and hypertension over wide ranges of age. Brandts et al compared 15 patients with hypertension and 15 age- and sex-matched healthy volunteers (mean age, 49 years). Aortic wall thickness and PWV were all significantly higher in patients with hypertension. However, in the cross-sectional part of the present study, hypertension was more directly associated with functional impairments (stiffer aorta) than AWT.

The trend of increased arterial wall thickness with atherosclerosis and cardiovascular disease was observed in most subjects. Atherosclerosis and plaque deposition can increase AWT, which, combined with alterations in blood pressure, may lead to progressive increases in stiffness. Although higher diastolic blood pressure was related to increased AWT and aortic stiffness was associated with hypertension, there were no overt cardiovascular symptoms in our study population.

Arterial stiffness is accepted as a major determinant of increased systolic and pulse pressure with aging and, therefore, is a major determinant of stroke and myocardial infarction. Aside from age and hypertension, arterial stiffness has been associated with numerous conditions, including heart failure.
failure and ischemic heart disease. Distensibility measures local stiffness, while PWV is considered to be an integrated marker of arterial stiffness when predicting fatal and nonfatal cardiovascular events. Those with hypertension in our study demonstrated greater aortic stiffness by reduced distensibility and increased PWV than those without hypertension. In subjects without hypertension, AWT was associated more strongly with distensibility than with PWV. Pulse wave velocity was not related to AWT in both groups in the fully adjusted model. This might suggest that AWT has greater impact on local stiffness in late adulthood. Although this finding contrasts with the study by Brandts et al, in which AWT was significantly related to PWV regardless of hypertension status, our participants were >20 years and PWV was higher than those in the Brandts et al study.

We recognize several limitations in our study. Current analyses included only non-Hispanic white and black subjects from a single site in the MESA study. Generalization to the entire MESA cohort, which includes Hispanic and Chinese participants, is therefore not possible. We only acquired AWT on a single cross-section of the descending aorta, and compared with the distensibility of the ascending aorta. Pulse wave velocity was also limited to the aortic arch. These standardized sampling sites were for both cross-sectional and longitudinal comparisons without increasing the scanning burden. Because of the heterogeneity in the vascular remodeling process and atherosclerotic changes across the arterial tree, the local measurement is not able to reflect the plaque burden as a systemic disease, particularly in the abdominal aorta.

Perspectives

In conclusion, using standardized magnetic resonance imaging methods, we demonstrated longitudinally from the MESA that during mid to late adulthood, thoracic aortic wall thickens in a yearly rate of 0.032 mm. Although men demonstrated thicker walls than women, there was difference between sexes in the rate of change in thickening. This change in aortic wall thickness over time has particular importance while considering risk factors for atherosclerosis in longitudinal research studies. Increase in AWT beyond this nominal change may identify individuals at higher risk for atherosclerosis. The data presented herein suggest aortic structural change is primarily related to age, race, and BMI. In those with hypertension, the aorta stiffens without necessarily impacting aortic wall thickness.

Novelty and Significance

What Is New?
• Using standardized magnetic resonance imaging methods, we demonstrated longitudinally from the Multiethnic Study of Atherosclerosis that during mid to late adulthood, the thoracic aortic wall thickens in a yearly rate of >0.032 mm.

What Is Relevant?
• This change has particular importance while considering risk factors for atherosclerosis in longitudinal research studies. The data presented herein suggest aortic structural change is primarily related to age, race, and body mass index. In those with hypertension, the aorta stiffens without necessarily affecting aortic wall thickness.
