Inhibition of the Kallikrein-Kinin System and Vascular Reactivity in Bartter’s Syndrome

JOSE A. RODRIGUEZ-PORTALES, JOSE M. LOPEZ-MORENO, AND DANIEL MAHANA

SUMMARY To study the significance of the increased activity of the kallikrein-kinin system described in patients with Bartter’s syndrome, we investigated the pressor response to infused angiotensin II in four patients with the syndrome receiving no treatment and during the administration of aprotinin and of indomethacin. Five normal subjects served as controls. Aprotinin is a proteolytic enzyme that inhibits the formation of kinins by inhibiting plasma and glandular kallikrein. Indomethacin, a prostaglandin-synthesis inhibitor, can also inhibit the kallikrein-kinin system and normalizes vascular responsiveness to angiotensin II in Bartter’s syndrome. All patients had increased urinary kallikrein and prostaglandin E2 concentrations. Aprotinin significantly decreased the dose of infused angiotensin II required to induce a 20 mm Hg increase in diastolic blood pressure, from 11 ± 4 ng/kg/min to 7.0 ± 2.0 ng/kg/min (mean ± SD; p < 0.05) in normal subjects and from 135 ± 57 ng/kg/min to 70 ± 26 ng/kg/min (p < 0.05) in the patients with Bartter’s syndrome, without significantly changing plasma renin activity, mean control blood pressure, or urinary prostaglandin E2 concentration. Indomethacin normalized the pressor response to angiotensin II in three patients who had been pretreated for 4 days (pressor dose, 10 ng/kg/min) but not in one patient who received a single oral dose of indomethacin 5 hours before the test. Our results suggest that inhibition of the kallikrein-kinin system alone accounts for approximately a 50% decrease in vascular resistance to the pressor effect of angiotensin II in Bartter’s syndrome, while additional suppression of prostaglandins entirely normalizes the vascular response to angiotensin II. These observations underscore the importance of the kallikrein-kinin system as a vasodilator in Bartter’s syndrome and support the concept that this system may contribute to the regulation of blood pressure in human beings.

(Hypertension 7: 1017-1022, 1985)

KEY WORDS • prostaglandins

FROM the earliest studies of Bartter’s syndrome, it was apparent that there were abnormalities in the vascular reactivity to pressor agents. The arterial blood pressure in patients with Bartter’s syndrome remains normal in spite of markedly elevated plasma concentrations of angiotensin II and aldosterone and increased production of norepinephrine.1,2

The vascular resistance to angiotensin II has been explained by a change in the angiotensin II-receptor interaction in vascular smooth muscle secondary to prior occupancy of the receptor sites by endogenous hormone.3,4 Others postulate that the elevated concentrations of vasodilating prostaglandins interfere with the vasoconstrictor effects of angiotensin II.5,6

A hyperactivity of the so-called kallikrein-kinin system also occurs in Bartter’s syndrome. Urinary kallikrein concentration is increased,7 possibly reflecting increased renal kallikrein; plasma bradykinin, a more potent vasodilator than the prostaglandins, is also increased.7

To assess the role of the kallikrein-kinin system in the vascular resistance to angiotensin II, we compared the pressor response to infused angiotensin II in five normal subjects and in four patients with Bartter’s syndrome receiving no treatment and during administration of aprotinin, a kallikrein inhibitor. In all of the patients, the pressor response to angiotensin II was also evaluated during treatment with indomethacin.

Patients and Methods

The clinical data of four patients with hypokalemia secondary to urinary potassium loss, hypochloremia, metabolic alkalosis, normal blood pressure, and secondary hyperaldosteronism are presented in Table 1.

*Chromogenic assay, Patients 1, 3, and 4. †Bioassay, Patient 2.

Patient 1 was a 25-year-old woman who had been diagnosed in childhood but had abandoned treatment for 2 years. Patients 2, 3, and 4 were children who, in addition, showed failure to thrive. Patients 3 and 4 were siblings. None of the patients had a history of vomiting, diuretic intake, or laxative abuse. Their liver function, as judged from prothrombin time and serum bilirubin, serum glutamic-oxaloacetic transaminase, serum glutamic-pyruvic transaminase, and alkaline phosphatase levels, was normal. Results of urinalysis and intravenous pyelograms were also normal in all patients.

All patients had a decreased fractional distal reabsorption of solutes, measured as the ratio of the free water clearance (CH₂O) to the distal delivery of solutes (CH₂O + C₅O₂ or CH₂O + C₅Na + K) under conditions of maximal free water clearance with an intravenous infusion of 5% dextrose in water. The four patients had renal biopsies, which showed juxtaglomerular hyperplasia in three. In Patient 4 no glomeruli were obtained in the specimen. The control group was formed by five healthy adults (aged 17–42 yr; 4 men and 1 woman) who had a personal and family history of normal blood pressure and did not receive medications for at least 2 weeks. The patients or their parents signed consent forms for the protocol, which had previously been approved by the Ethics Committee of the Catholic University of Chile.

The patients were admitted to a metabolic ward where they received a diet constant in sodium (87 mEq/m² of body surface area/day) and potassium (70 mEq/day). Blood pressure was monitored with an arm cuff mercury manometer every 4 hours throughout their hospital stay. A Foley catheter was inserted in the bladder for the clearance study and for the prostaglandin E₂ (PGE₂) and kallikrein urine collections.

Blood was collected on admission and on the study days for electrolytes, bicarbonate, and plasma renin activity (PRA). Urine was collected daily for electrolytes. Basal urinary aldosterone, PGE₂, and kallikrein were measured after equilibration on the diet was achieved. Sodium and potassium were measured by internal standard flame photometry in a spectrophotometer (Beckman Instruments, Inc., Fullerton, CA,
was measured basally, after infusion of aprotinin and after aprotinin plus the pressor dose of angiotensin II.

Indomethacin, 3 to 5 mg/kg/day, was given orally for 4 days to Patients 1, 2, and 3. On Day 4, the angiotensin II infusion was repeated in the manner just described. Patient 4 received the infusions 5 hours after a single oral dose of 100 mg of indomethacin (5.2 mg/kg). The PRA was measured before and at the end of the infusion.

To study whether repeated angiotensin II infusions per se can decrease pressor responsiveness, the pressor dose of angiotensin II was determined as previously described, on a separate day, in Patient 3. After a 20 mm Hg increase in the diastolic blood pressure had been obtained, the infusion was stopped for 30 minutes, which allowed the blood pressure to return to control values. Then the pressor dose of angiotensin II was again determined as before. A second period of 30 minutes without angiotensin II was observed, followed by a third infusion period to determine the pressor dose.

The effect of increasing doses of aprotinin on angiotensin II responsiveness was studied in Patients 3 and 4. The pressor response to angiotensin II was determined as described. Aprotinin was added to the 5% glucose in water infusion, and the rate was adjusted to deliver 5, 10, 15, and 20 KIU/kg/min. Each dose was infused for 30 minutes before starting the angiotensin II infusion. Angiotensin II was given initially at a subpressor dose and increased stepwise until a 20 mm Hg increase of the control diastolic pressure had been obtained.

Results

Mean baseline diastolic blood pressures were 60, 70, 70, and 80 mm Hg, respectively, in Patients 1, 2, 3, and 4 (Figure 1). Infusion rates of 120, 60, 180, and 180 ng/kg/min of angiotensin II, respectively (mean ± SD, 135 ± 57 ng/kg/min), were required to increase their diastolic blood pressures by 20 mm Hg. Their systolic blood pressures were 90, 97, 105, and 103 mm Hg and increased to 114, 130, 108, and 120 mm Hg, respectively, with the pressor dose of angiotensin II. Levels of PRA were 67.2, 650, 54.9, and 115 ng/ml/hr before and 93.0, 631, 51, and 105 ng/ml/hr at the end of the infusion.

In normal subjects, the mean baseline blood pressures were 112 ± 11 mm Hg (systolic), and 66 ± 11 mm Hg (diastolic). The mean pressor dose of angiotensin II in this group was 11 ± 4 ng/kg/min. The PRA was 0.64 ± 0.74 ng/ml/hr before the infusion and 0.56 ± 0.38 ng/ml/hr at the end of it.

From control mean diastolic blood pressures of 60, 80, 70, and 80 mm Hg, doses of 60, 40, 80, and 100 ng/kg/min of angiotensin II were needed in Patients 1, 2, 3, and 4, respectively (mean ± SD, 70 ± 26 ng/kg/min; p < 0.05 with respect to control), to induce a similar 20 mm Hg rise in diastolic blood pressure during the simultaneous infusion of aprotinin (Figure 1). Therefore, a 50%, 33%, 55%, and 44% decrease in the vascular resistance to angiotensin II was obtained.
when angiotensin II was given together with aprotinin. Systolic blood pressures were 90, 100, 98, and 110 mm Hg in Patients 1, 2, 3, and 4 and increased to 100, 140, 108, and 120 mm Hg, respectively, with the pressor dose of angiotensin II. Levels of PRA were 104.9, 582, 61, and 112 ng/ml/hr before and 105.9, 570, 48, and 122 ng/ml/hr at the end of the aprotinin infusion in Patients 1, 2, 3, and 4 respectively. With the addition of angiotensin II, PRA changed to 106, 403, 50.7, and 115 ng/ml/hr on attainment of the pressor dose.

In normal subjects, the mean baseline blood pressures were 114 ± 11 mm Hg (systolic), and 68 ± 9 mm Hg (diastolic). The mean pressor dose of angiotensin II during aprotinin was 7 ± 2 ng/kg/min (p < 0.05 with respect to control). The PRA was 0.48 ± 0.2 ng/ml/hr before and 0.55 ± 0.3 ng/ml/hr at the end of the aprotinin infusion. With the addition of angiotensin II, PRA decreased slightly but not significantly to 0.32 ± 0.29 ng/ml/hr. Aprotinin did not change urinary PGE₂ significantly (control, 1.59 ± 0.7 ng/min, aprotinin, 5.15 ± 3.12 ng/min).

The angiotensin II infusion was repeated during treatment with indomethacin in all patients. In Patients 1, 2, and 3, who had received indomethacin for 4 days, the pressor dose was 10 ng/kg/min: blood pressure rose from 100/72, 102/74, and 88/61 mm Hg to 140/100, 120/94, and 96/81 mm Hg respectively.

Patient 4, who had received a single oral dose of 100 mg of indomethacin 5 hours earlier, had no response because his diastolic blood pressure increased by 20 mm Hg (from 101/78 mm Hg to 130/100 mm Hg) when 180 ng/kg/min of angiotensin II was infused. Levels of PRA were 7.2, 6.8, 15.0, and 96 ng/ml/hr in Patients 1, 2, 3 and 4, respectively, before and 5.5, 5.2, 11.0, and 81 ng/ml/hr at the end of the angiotensin II infusion. Figure 2 shows the increasing pressor responsiveness to angiotensin II in Patient 3 with aprotinin and with indomethacin.

The pressor responsiveness to repeated doses of angiotensin II was studied in Patient 3. A 20 mm Hg increase in diastolic blood pressure was found when 100 ng/kg/min of angiotensin II was infused. After 30 minutes without infusion, the pressor dose was found to be 192 ng/kg/min. After a second control period of 30 minutes, the pressor dose was 276 ng/kg/min.

The effect of increasing doses of aprotinin on angiotensin II responsiveness was studied in Patients 3 and 4. Figure 3 shows that Patient 3 required progressively less angiotensin II to induce a 20 mm Hg rise in diastolic blood pressure as the dose of aprotinin infused was increased: from a baseline pressor dose of 716

![Figure 1](image-url) Effect of aprotinin and of indomethacin on vascular reactivity to infused angiotensin II in Bartter's syndrome. The result for indomethacin excludes Patient 4. The symbols indicate the level of statistical significance between the corresponding bars: the asterisk shows a p value of less than 0.01 between control and indomethacin; the square, p less than 0.05 between control and aprotinin; and the circle, p less than 0.02 between aprotinin and indomethacin.

![Figure 2](image-url) Effect of aprotinin and indomethacin on the pressor response to infused angiotensin II in one patient with Bartter's syndrome. A II = angiotensin II.
ng/kg/min, increasing doses of aprotinin decreased the angiotensin II pressor doses to 42 ng/kg/min.

In Patient 4 the pressor dose of angiotensin II without aprotinin was 655 ng/kg/min. With aprotinin, 5 KIU/kg/min, the pressor dose decreased to 308 ng/kg/min. With aprotinin, 10 KIU/kg/min, the pressor dose remained at 308 ng/kg/min. With 15 KIU/kg/min it decreased to 214 ng/kg/min of angiotensin II, but with aprotinin, 20 KIU/kg/min, the pressor dose increased to 308 ng/kg/min.

The initial pressor doses of angiotensin II before aprotinin infusion were considerably higher than in prior studies of Patients 3 or 4, possibly due to nausea and vomiting with an increased production of vasodilating prostaglandins since no change in technique occurred.

Discussion

Resistance to the pressor effects of angiotensin II in Bartter’s syndrome has been attributed to changes in receptor-hormone interaction as a result of chronically elevated concentrations of angiotensin II and to the vasodilating effect of prostaglandins and other substances. Accordingly, the pressor response to angiotensin II in Bartter’s syndrome can be enhanced by procedures whose main effect is to decrease endogenous angiotensin II, such as acute volume expansion, or to potentiate vascular responsiveness, such as by sodium loading, or to decrease the concentration of endogenous vasodilators, such as by the use of indomethacin.

Indomethacin not only inhibits prostaglandin production but also decreases the activity of the renin-angiotensin system, the excretion of urinary kallikrein, and the concentration of plasma bradykinin, effects that are also shared by volume expansion and by sodium loading. In fact, since all these mechanisms may account in part for the normalization of the pressor response to infused angiotensin II in Bartter’s syndrome, the use of either indomethacin, volume expansion, or sodium loading does not permit us to study separately the role of the vasodepressor substances or endogenous angiotensin II in the development of vascular resistance to pressor agents in Bartter’s syndrome.

Aprotinin is a proteolytic enzyme that inhibits the formation of vasodilating kinins by inhibiting plasma and glandular kallikrein. Direct evidence of kallikrein inhibition can only be obtained by measurements of plasma bradykinin. However, these measurements are still unreliable and technically cumbersome. In addition, plasma bradykinin levels may not correlate well with bradykinin generated locally at the blood vessel wall. In humans, aprotinin is a potent inhibitor of tissue kallikrein as well. Our results show that aprotinin can decrease vascular resistance to angiotensin II in Bartter’s syndrome. Additional indirect evidence that this effect may be mediated by kallikrein inhibition is provided by the dose-response relationship observed in Patient 3 (Figure 3). Patient 4, who had the lowest urinary kallikrein level and the lowest glomerular filtration rates, did not show such a clear dose-response relationship.

Aprotinin did not change PRA, blood pressure, or urinary PGE concentration, which confirms previous findings in Bartter’s syndrome. It is not surprising that aprotinin had no effect on the control blood pressure before the angiotensin infusion in the face of an unchanged PRA level because of the neural and humoral mechanisms that compensate for minor changes in blood pressure even if the kallikrein-kinin system is inhibited. It is unlikely that the effect of aprotinin on vascular reactivity could be mediated by prostaglandin inhibition, not only because urinary PGE did not change, but also because aprotinin had an immediate effect on vascular resistance while the effect of indomethacin was delayed, as observed in Patient 4.

That a decrease in vascular resistance is not a result of repeated angiotensin infusions per se is supported by the results obtained in Patient 3. In addition, evidence from the literature suggests that vascular resistance increases with increases in angiotensin II.

Other authors have given aprotinin to human subjects in doses manyfold higher than those we used. It is possible that if we had used higher doses of aprotinin a greater degree of vascular reactivity to angiotensin II could have been achieved. That we observed a decrease in vascular resistance with small doses of aprotinin underscores the importance of the kallikrein-kinin system in the pathogenesis of vascular resistance to pressor agents in Bartter’s syndrome and emphasizes the need for further studies on the role of kinins in the pathophysiology of the syndrome.
Thus, it seems reasonable to conclude that in Bartter's syndrome, the increased activity of the kallikrein-kinin system can contribute to the angiotensin II resistance. In normal human subjects, in whom the activity of the kallikrein-kinin system is much lower than in persons with Bartter's syndrome, aprotinin also induced an increase in vascular sensitivity to angiotensin II. Therefore, the results of this study also support the concept that the kallikrein-kinin system is a modulator of blood pressure regulation in human beings.

In summary, in four patients with Bartter's syndrome who had increased urinary kallikrein levels, the administration of aprotinin improved pressor responsiveness to exogenous angiotensin II, possibly as a result of the inhibition of the vasodilator effects of bradykinin on blood vessels. On the other hand, suppression of both the prostaglandin system and the kallikrein-kinin system with indomethacin entirely normalized the vascular response to angiotensin II.

Acknowledgments

The authors are indebted to Dr. Meyer Lipschitz, from the Renal Division, Department of Medicine, University of Texas Health Science Center at San Antonio, for the urinary prostaglandin determination.
